reported (and rightly, too) that the specimen showed nothing beyond the changes usual in inflammation. Had the growth increased and been again removed, microscopic examination would have shown clear signs of malignancy. This would have been set down as a case in which an innocent growth degenerated into a malignant one, when, in truth, it was malignant from the start.

J. Solis-Cohen, Bosworth, Gottstein, Lennox-Browne, Seiler, Fauvel, and other authorities in this branch of medicine, all state that such a change is possible, and some of them think that it frequently occurs. None, however, gives any facts to support his assertion, but, like so many other medical traditions, the statement is handed along from one to another and accepted by the latest authority on the mere assertion of those who have preceded him.

In a study of benign tumors of the mammary gland, Brandt[8] considers that malignant degeneration may take place in them, but only with extreme slowness. He considers, however, that most breast-tumors should be removed as a measure of wise precaution.

I believe, therefore, that I am warranted in saying that there is almost complete unanimity of opinion on this question among surgeons and pathologic anatomists. Those who allude to it at all, do so favorably, while the others seem to consider it as being so well accepted a fact as hardly to need mentioning. No one, so far as I have been able to learn, denies it.

Now, while that which is believed by common consent to be true has a certain weight as corroborative evidence, it is not proof, and unless we can find something stronger to sustain our case, we must rest content with the verdict "not proven."

There have been many doctrines in medicine that have been accepted as true by the entire body of the profession, which we now know to be completely false, so that it behooves us to look a little further in our search for facts.

Is there anything in the origin and growth of neoplasms, as we now understand them, that would tend to favor or negative the possibility of such a transformation as the one we are studying? The answer to this question will involve an excursion into the modern theory of tumors and tumor-growth.

The classification of new-growths most in accord with our present knowledge is the blastodermic. This is based on the fact that all the tissues and organs are developed from the three blastodermic layers, and that the tissues derived from any one layer are more or less histologically analogous. In neoplasms the analogy becomes complete and the cells revert to the type-cell of the layer from which they were derived. This enables us to classify these growths with approximate exactness. For example, if the connective-tissue cell be the predominating characteristic of the growth, then we know that we have to do with a tumor of mesoblastic origin. So, a growth composed of epithelial cells of a certain character will be referred to the epiblastic layer. Speaking in general terms, the epiblastic growths are either benign or non-metastatic; the hypoblastic are both malignant and metastatic; while the mesoblastic group contains benign and malignant, metastatic and non-metastatic tumors. I desire to call especial attention to this peculiarity of the mesoblastic group, for it is among tumors of this class that we find most of the evidences of change from benignity to malignity. In this class belong fibromas, lipomas, myxomas, chondromas, and osteomas, of the innocent growths, while all the forms of sarcoma represent the malignant types. The type-cell of all of them is the connective-tissue cell. This is their characteristic. In one form or another it occurs in all of them. The distinction between the cells of benign and malignant growths of this group is not marked. According to Wilks and Moxon,[9] it is the quality of the intermediate tissue that determines the character of the tumor as fibroma, myxoma, or sarcoma. In the simple-tissue tumors the cells are few and the inter-cellular substance greatly predominates; but when from any cause, the cells begin to be produced more rapidly and the inter-cellular substance to become more scanty, then we have a sarcoma. Thus, we see that the difference between a fibroma and a sarcoma is more one of degree than of kind. It is the opinion of these observers that "any of the previous group of tumors (fibroma, myxoma, etc.) would become sarcoma by the rapid growth of the cellular elements and deficient development of the inter-cellular matters."

Butlin,[10] in speaking of chondromas, says that bone, fibrous tissue, gland-tissue, and sarcoma-tissue, all or severally, may occur in combination with cartilage, and that sarcomas may become organized into fibrous tissue, cartilage, or bone. Ossifying and chondrifying sarcomas are sometimes taken for osteomas and chondromas, but "they remain," he says, "in effect, sarcomas, nine-tenths of whose structure has been transformed into some simple tissue, but with all the capabilities for evil which the most lowly-organized sarcomas possess."

It is a peculiarity of all neoplasms that the tissue of which they are composed is less highly organized than the normal tissues of the body. Now, bearing this fact in mind, and given a habit of body predisposing to malignant disease, is it unreasonable to suppose that this malignant tendency should show itself in a degenerate form of tissue rather than in the normal healthy tissue, particularly when both the innocent and the malignant growth are derived from

the same layer? Or, to take a concrete example, will sarcomatous degeneration be more likely to show itself in an already existing fibroma of the mamma than in the healthy gland-tissue? It seems to me not unreasonable to assume on *a priori* grounds that the malignant disease will be first shown in the more lowly-organized tissue.

One of the prime factors in determining malignant degeneration in healthy tissue is irritation. Now, it would seem that healthy tissue should resist the effects of irritation longer than unhealthy, and we should accordingly expect that if malignant change should take place in a benign growth, irritation or excitation of the tissues would have a large share in it. This is in accord with the clinical facts. In almost every case in which a benign growth has been assumed to have become malignant, the evil change has been laid at the door of irritation.

So far as we have gone, we have seen that the almost uniform testimony of surgeons and pathologists is in favor of the possibility of malignant degeneration of benign growths, and that there is nothing in the modern theory of tumor-growth inconsistent with such a change; but the medical mind of to-day cries out for facts. These are the days of skepticism in matters medical; and every theory and belief, no matter how ancient and venerated, must be tried anew by the touchstone of modern investigation. It is the main purpose of this communication to endeavor to find out whether this theory has enough facts in its favor to sustain it, or whether it must fall and be retired to the limbo of creeds outworn. The conditions of our inquiry narrow the field of investigation very materially. We must exclude all cases in which a non-malignant growth has been removed and a malignant growth has arisen in its site or in the scar. There are numerous instances of this kind on record, and any surgeon of experience could doubtless furnish one or more from his case-book.

In the second place, it is essential that the facts in each case be beyond cavil. This excludes all cases recorded before the time when the minute anatomy of neoplasms became so well understood as it is now. The time is not so very far distant when all malignant growths were called cancer. Mere clinical observation is not sufficient to determine the question of the innocence or malignancy of any particular growth.

Thirdly, the observations on which any conclusive opinion may be based should be made by those who, by reason of experience or special skill, are of such eminence as to give their opinions an questioned authority.

And, fourthly, it will not do to include cases in which an innocent growth in one part of the body is invaded by secondary deposits from a malignant neoplasm situated elsewhere. A case of this character is the one recorded by Fenwick[11], in which a small fibrous nodule surrounding the orifice of one of the ureters became invaded by secondary deposits from a carcinomatous growth in the liver and stomach.

Hampered by these restrictions, I doubted the possibility of finding in medical literature observations recorded with such care as to decide the question either one way or the other. It is proper to state here that personally I have no knowledge of any such change, and I can well understand how a surgeon of wide experience might never see such a case. In order to fulfil the conditions essential to certainty, he must be able to see the case in its very incipiency, and to follow it to its very end. Even then there might remain a doubt as to the correctness of the diagnosis. Let us suppose, for instance, that a surgeon sees a case of breast-tumor in its earliest stage, possessing none of the manifestations of a malignant growth, and having all those of an innocent glandular tumor. As time goes on, the tumor, still under his observation, begins to grow rapidly, cause pain, contract adhesions, disturb the general health, and, in short, behave so as to demand removal. The growth is removed, examined carefully, and found to possess clear elements of malignancy. Now, the surgeon is satisfied in his own mind that the growth was innocent at first, but he cannot absolutely prove it. Of course, the chances are in favor of his being right, but probability is as far as he can go. This is not a far-fetched assumption, as is shown by the case reported by Jonathan Hutchinson, Jr.[12] In 1873, a woman of fifty-four came under the care of Mr. Hutchinson, Sr., for a tumor in the left breast, which had been noticed for six months, and was then three inches in diameter. It was removed, and proved to be an encapsulated adenoma, with a few cysts. Thirteen years afterward the woman was in good health. She had a daughter who had noticed from girlhood a small round tumor beneath the skin of the left breast, which was "as large as a cherry, and did not grow." When she was forty-four years of age considerable growth took place around the tumor, and Mr. Hutchinson found a hard mass adherent to the skin. He diagnosticated scirrhus of two years' standing. The breast and axillary glands were removed. The patient was well at the end of ten years. Microscopic examination showed round-celled adenoma imbedded in scirrhus. The appearances clearly showed that the carcinoma had invaded the adenoma. In this case the element of heredity is added to the other probabilities in favor of a change from benignancy to malignancy, but it still remains only probability. Again, scirrhus might have invaded the gland had there been no adenoma there

at all. As Paget,[13] in speaking of these adenomas, fitly remarks: "On the whole, one might expect that if a woman have a tumor of this kind in her breast, cancer would be more apt to affect it as a morbid piece of gland than to affect the healthy gland."

In the report of the Middlesex Hospital for 1884 is an account of a case in which carcinoma supervened upon a multilocular cystic adenoma of thirty-four years' standing. Similar to this is the case occurring in Dr. Hartley's service in the New York Cancer Hospital, as related by Dowd.[14] Here the patient was thirty-eight years of age. When ten years old he had noticed a hard, insensitive, pea-sized tumor in his neck below the right submaxillary gland. This showed no change for fifteen years, when it became as large as a hickory-nut, but showed no other change for ten years or more, when it began to grow rapidly. It was excised twice during the following three years, and when seen in September, 1891, consisted of two lobes, each as large as a hen's egg.

In the same article is an account of another case in a woman of sixty-seven, who had had several wens in her scalp for ten years. In July, 1891, one of them became painful and tender and soon ulcerated. On removal it was found to be an epithelioma extending down to the periosteum. The other tumors were ordinary wens, as shown by microscopic examination. Shattock[15] also reports a case of cystic, squamous-celled carcinoma, arising in a sebaceous cyst of the scalp.

Taking into consideration the elements of uncertainty surrounding all merely clinical observations, it is to the pathologic anatomist rather than to the surgeon that we must look for the evidence necessary to settle this question. Can he show us a growth containing within itself, at the same time, unmistakable evidences of innocent and of malignant action, and presenting these changes in such a way as to show that the one has shaded into the other?

It is obvious that these conditions are hard to satisfy, but if only one such growth can be shown it will be sufficient to establish the fact.

In 1888, Mr. T. Charlewood Turner[16] showed to the Pathological Society of London a tumor of the size of a hazel-nut from the spinal cord of an obese woman. The left half of the growth was distintly fatty, but the right half consisted of interwoven strands of fibrous tissue, rather profusely studded with oval elongated nuclei and leukocytes—in short, sarcomatous tissue. This, at first sight, would seem to answer the conditions of our inquiry and to decide our question in the affirmative; but it is impossible to say whether the fatty change was primary or secondary. If primary we have a case fulfilling all of our conditions; if secondary, we are as far from an answer as ever. Taking into consideration the excessive fatness of the patient and the well-known fact that sarcomata not infrequently undergo fatty degeneration, the probabilities seem to be that the tumor was originally sarcoma and the fatty deposit secondary and not primary.

For many years past gynecologists have been removing from the abdomen fibroid, or, more correctly speaking, myomatous tumors. These are undoubtedly benign growths and are so accepted by all pathologists. Let us see if we can find any evidence of malignant degeneration in these growths.

Mr. Alban Doran,[17] a gynecologist of repute, reports a case of uterine myoma, in which there was beginning sarcomatous degeneration. He gives a full history of the case, with drawings of the microscopic appearances, which seem to bear out his conclusions. In a series of two hundred and five operations for the removal of fibroids of the uterus by Martin,[18] of Berlin, four of the tumors were intra-parietal encapsulated myomata, undergoing sarcomatous degeneration. Schroeder[19] states that primary degeneration of fibroid tumors into carcinomata hardly ever occurs (but one case having been reported), but that the change from a fibroid to a sarcoma is not infrequent. "We cannot as yet," he says, "determine how often this change from a benign fibroid into a malignant sarcoma takes place. There is no doubt that it may take place." He considers that the formation of the fibroid sarcoma of the parenchyma of the uterus is in some way due to the presence of a round fibromyoma or a fibrous polypus. "At any rate," he says, "it not infrequently proceeds from a degeneration of these."

The latest case is that of Ehrendorfer,[20] recently reported. This is given in full and is accompanied by a careful description of the microscopic appearances, leaving no room for reasonable doubt that the case was one of primary carcinomatous degeneration of a uterine myoma; but it is useless to present further citations. The fact seems well enough established that benign growths may undergo malignant degeneration. It is but right to say that many other gynecologists equally eminent deny the possibility of any such change, but the weight of the evidence seems to be in its favor. Such is the character of the evidence that I have to offer for and against this theory. I regret that time has not been available for a more extended search of the literature of medicine.

It seems to me that the following conclusions may legitimately be drawn:

1. That benign tumors may undergo malignant degeneration has been accepted as true by most clinical observers and pathologists.

2. That there is nothing in the modern theory of tumors and tumor-formation to contra-indicate the possibility of such a change.

3. That the facts now on record are sufficient to show that such a change may and does occur, although but rarely.

4. That the change is more frequent in growths of mesoblastic origin, and more particularly in the so-called uterine fibroids than in any other class of neoplasms.

FRACTURE OF THE PATELLA TREATED BY CONTINUOUS EXTENSION; PATIENTS NOT CONFINED TO BED.

BY JOSEPH D. BRYANT, M.D.,
OF NEW YORK.

Two varieties of treatment of fractured patella are generally recognized, the mechanical and the operative. It is not my intention to allude to the latter method, except in a general way; nor, in fact, to the devices of the former plan except as they may be employed to illustrate the method of treatment that I present. The indications to be met in the treatment of this fracture are the stereotyped ones that are applicable to all fractures, namely, the reduction of the fragments and the holding of them in place until a proper degree of union ensues to permit of the removal of the retaining forces. In fracture of the patella the uppermost fragment is drawn upward by the influence of the quadriceps extensor muscle, while the lower is somewhat displaced downward by means of the non-muscular tissues attached to it. Ordinarily, crepitus can be easily elicited between the fragments, provided the attempt be made before the formation of the firm blood-clots that become closely connected with the broken surfaces of the bone within a few hours after fracture. The failure of the medical attendant to obtain crepitus at this time should be attributed to the presence of these clots rather than to the influence of the stretched aponeurotic tissues connected with the upper surface of the patella. The presence of these clots and their influence in separating the fragments are frequently and easily demonstrated during the operative technique of wiring the patella for fracture.

The steps necessary for the reduction are, first, the extension of the leg and elevation of the limb to secure complete relaxation of the quadriceps extensor muscle; second, the drawing together and retention of the fragments in position until some form of union insures sufficient strength to properly maintain them in place. It is hardly necessary for me to describe the various instrumental means heretofore employed to effect the reduction and retention of the fragments in this fracture. It is sufficient to say, however, that their basis-action consists in extension applied directly or indirectly to the upper fragment and the holding of the lower fragment upward in position. The extension is represented in these cases as applied to the upper fragment and to the thigh, and also to both of these parts simultaneously. It is manifest to one familiar with the relationship of the tissues composing the thigh that extension applied to the thigh alone can exercise but little other restraining influence on muscular contraction than that dependent on coaptation pressure, because the dense fascia lata intervenes between the muscles of the thigh and the integument to which the extension is applied. However, when extension-apparatus is applied to the upper fragment of the patella with sufficient firmness to meet the indication, then, indeed, some command of the quadriceps muscle is secured. But even in this instance the inequality, severity, and direction of the pressure necessarily brought against this fragment, together with the absorption of the surrounding soft parts incident to the pressure, quickly render its influence insecure and migratory, unless constant and tedious, not to say painful attention be given to the case.

In my judgment, the feature most commendable in the wiring method is this: It permits patients to move around on crutches within a few days, thereby relieving them of the tedium and depression of long confinement.

Of the mechanical appliances permitting patients to be at once about on crutches, plaster-of-Paris, applied in the form of a thigh or hip spica, extending down to cover the foot, with an oblique patella-traction arrangement of the bandage at the knee, is most often selected. With this method, even in a very few days, the limited direct-extension influence that the splint exercises on the upper fragment disappears, owing to the shrinkage of the limb, and in

part to the pressure of the splint itself. The coaptation-influence on the tissues of the thigh, exercised by the splint at the time of its application, is soon much lessened on account of the same shrinkage. I have quite often witnessed the treatment of this fracture with the plaster-of-Paris splint when little attention was paid to the tissue-changes following its application, even up to final recovery; and candor compels me to state that in these cases the results were quite as satisfactory in all respects as in cases treated more actively and with seemingly better philosophy. I have often remarked that the results of the treatment of fracture of the patella with a plaster-of-Paris spica were much more convincing of the fact of how little treatment the fracture required than of the efficiency of this particular method. However this may be, it is surely a great desideratum to employ a means that, while it holds the fragments as well as possible by mechanical measures, still subjects the patient to as little confinement as if wiring of the patella had been done. The plan that I have employed, with some interruptions, for a number of years past can be divided for the sake of simple elucidation into five separate steps.

FIG. 1.

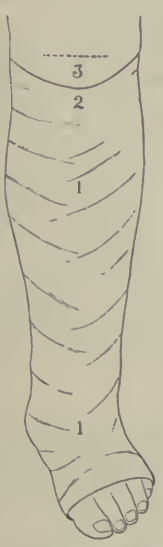

FIG. 2.

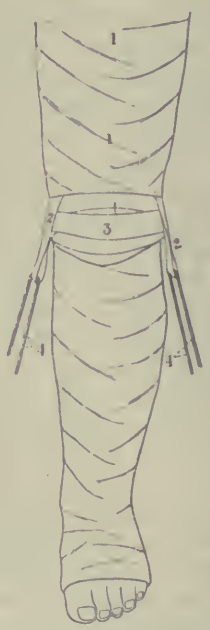

FIG. 1.—1, 1. Plaster splint as applied to leg. 2. Upper border of splint pressing lower fragment into position. 3. Lower fragment with line of fracture above.

FIG. 2.—1, 1. Extension as applied to thigh. 2, 2. Front view of extension straps. 3. Adhesive straps retaining fragments in position. 4, 4. Rubber extension made taut while adhesive straps are being applied.

First step (Fig. 1). The first step consists in the application to the leg of a plaster-of-Paris splint, extending from the base of the toes up to and partly around the lower fragment (3). The splint is firmly applied to the limb a sufficient time in advance of the succeeding steps to permit of its becoming thoroughly hardened. It is carefully rounded at the lower extremity (2), so as to press into position and hold there the lower fragment (3). Its functions can be said to be threefold: 1st. It serves to protect the foot of the patient from the pressure of the rubber extension, which acts from this part of the limb. 2d. It confines in place the lower fragment, and the pressure upward of the splint, due to the elastic force of the extension transmitted through it to the foot, retains the upper border of the splint in proper relationship to the lower fragment. At all events, any diminution of pressure on the part of the splint in this situation can be readily supplemented by the introduction of suitable pads between it and the lower fragment of the patella. 3d. It affords attachment to the lower end of the supporting rod or brace, intended to maintain complete extension of the limb while acting as a posterior support.

Second step (Fig. 2). The features of the second step are quite as strongly expressed by the illustration representing it as words can define them. This step consists in the application to the thigh of an extension-apparatus fashioned after the manner of the well-known Buck's extension, which reaches from the perineum to the upper border of the upper fragment (1, 1).

It is confined in position by the ordinary muslin roller. The adhesive element of this appliance terminates a little below the knee in a loop (2, 2) at either side, through which may be passed the rubber extending cord (4, 4), or to which may be connected hooks for the convenient attachment of the rubber cords or bands that are to pass around the bottom of the splint, and by means of which the extension is made and maintained. The broad triangular adhesive strips to which the extension loops are sewed are confined in position at the sides of the thigh by means of simple roller bandages. Moderate extension is then made on the loops by means of the rubber cords, in order to draw as far as possible downward the soft tissues of the thigh and the upper fragment of the patella. While the extension is thus being made, the roller bandage intended to hold the adhesive-plaster strips in place is covered by plaster-of-Paris rollers from the upper to the lower limits of the adhesive-plaster extension, and so fashioned as to control the upper fragment in the most serviceable manner while extension is in action. The object of this plaster-of-Paris addendum is, first, to aid in holding the primary dressing of the thigh in a firm position; second, and principally, to afford an upper support for the extending rod or splint to be placed behind the

limb, and to aid, also, in confining the upper fragment of the bone in proper relationship to its fellow, as will appear in the succeeding step.

The second step meets the following indications: First, it coaptates the tissues of the thigh, thereby exercising a controlling influence over muscular contraction, and is the agent causing extension of the integument and the subcutaneous tissue. Second, it makes direct extension of the quadriceps through its firm application to the upper fragment of the fractured bone and the tissues immediately above and around it.

Third step. This step consists in strapping the fragments of the patella in such a manner as to draw them well together and properly maintain them in position. These strips of plaster (3, Fig. 2) are fastened in position behind to a wooden support or brace, about two inches in width, one inch in thickness, and extending from near the upper

FIG. 3.

border of the thigh portion of the splint to the lower part of the splint surrounding the leg. These adhesive strips should be applied cautiously, so as not to irritate the integument, and also to prevent either of them from being drawn downward between the fragments of the broken bone. If this accident happens, greater separation of the fragments ensues, and union of a serviceable kind is much delayed, and may be defeated. These strips can be applied with greater care, convenience, and effectiveness, if traction be made away from the median line of the thigh, as represented in Fig. 2 (4, 4).

Fourth step (Fig. 4). This consists in fastening the posterior support or brace (2) in proper position, and fixing it there by means of plaster-of-Paris rollers carried around it and the upper and lower segments of the splint where they lie in contact with each other. These bandages harden quickly, and thus incorporate the posterior support firmly with their structure, forming an interrupted plaster-of-Paris splint, with a posterior connecting brace (1, 1, 2). The interval at 2 shows this brace with the patellar adhesive straps attached, by means of which the strips are retained in position.

Fifth step (Fig. 4). The posterior support in this illustration is unusually thick (2), being composed of wood. A small iron rod on each side of the posterior surface of the limb will answer much better for many reasons, and is less cumbersome. However, this one illustrates sufficiently well the importance of the posterior support, and better, perhaps, than a less conspicuous object. Fig. 4 shows the posterior support as placed against the posterior surfaces of the plaster splints previously described, and confined there by fresh plaster rollers. This should be accomplished while the extension force is in action. These bandages are represented as carried around the limb from the extremities of the support to the contiguous borders of the underlying plaster splints. As already mentioned, the hardening of these newly applied bandages incorporates the posterior support with the plaster-of-Paris structure so firmly that an unyielding common apparatus is formed. The object of this support is obvious to anyone. It serves to keep the limb extended, thus preventing undue traction on the fragment of the quadriceps muscle, and it affords attachment to the adhesive plasters that confine the fragments of the patella in proper position. Leather collars, properly fashioned and padded, passing around the limb above and below the patella, and drawn firmly toward each other by means of leather straps, as figured in the text-books, may be employed instead of this method of strapping. In either instance the hamstring tendons should be carefully protected from undue pressure by the interposition of some soft suitable material. After the apparatus is completely and suitably applied, the patient may be permitted to walk around, but the limb during this time should be flexed somewhat on the trunk by means of a long sling extending from the foot, which it supports, and carried over the neck of the patient. The employment of this expedient will flex the entire limb considerably on the trunk, and thereby cause greater relaxation

of the quadriceps extensor muscle, and also obviate the influence on the upper fragment of the involuntary contraction of the muscles that are associated in the effort of locomotion.

THE ADVANTAGES OF THIS APPLIANCE.

The following advantages appear to me to be quite clearly defined:

1. It apposes the fragments of the patella from the first as well as any other non-operative appliance can accomplish this purpose.

2. It maintains them in position better than any mechanical means yet employed, unless the patient be confined in bed and a constant and tedious scrutiny be exercised by the physician in charge.

3. It permits the patient to be up and around sooner and more comfortably than any non-operative method of treatment yet employed.

I have thus far treated nine cases by this method, with results equal to those of any other non-operative method, and with much more comfort to the patients. Like all methods, this one, too, has its fallacies. It is important to regulate the degree of elastic extension in accordance with the requirements of each particular case. If greater extension be employed than is essential, the straps by means of which the extension is secured may be torn or drawn away from their fastenings. At all events, great discomfort will be caused. It is proper to say, however, that a degree of extension may be employed which will be readily withstood by the straps at the earlier period of their application, which is out of all proportion to the requirements of the case, and at a later period would promptly cause slipping of the adhesive straps. In one instance, as a matter of experiment alone, I applied a degree of elastic traction to a case equivalent to forty pounds. It may be thought, perhaps, that the application around the thigh of the plaster-of-Paris casing, and introduction of the posterior support connecting the two portions of the splint, will interfere with the extension influence applied to the thigh itself. This, however, is not the case, as the extension acts independently of the incasing plaster, while at the same time the incasing plaster serves to confine the adhesive strips properly in position. If the interval between the plaster splints corresponding to the knee and popliteal space be not thoroughly and carefully covered, either with straps, cotton, or bandages, pain and edema will, for obvious reasons, take place there.

After the adhesive strips are properly applied to the patella, the intervals between the splints, behind and in front, should be filled in with layers of absorbent or other kind of cotton, and bandaged closely in place. At the time the posterior support is placed in position, cotton or other suitable material for exercising moderate pressure should be interposed between it and the posterior surface of the knee, already the patella-retaining straps are applied, as then this material can be drawn firmly into place. As before remarked, the fragments should be carefully and properly strapped, and great care exercised in the application of the straps, else one of them may be drawn between the fragments, and before its discovery may cause greater separation and interfere with the union.

Finally, it is necessary that the plaster splints should be kept firmly apposed to the underlying surfaces, which, of course necessitates their being cut up quite soon after their application. The cutting up can be easily done by means of an ordinary knife after the manner usually employed in other forms of splints of a similar nature. If a proper portion of the splint be removed in the line of incision, the splint can then be firmly drawn in place around the limb by means of an ordinary muslin roller.

In presenting to your consideration this method of treatment of fractures of the patella, I do not claim any originality as to the application of extending force in this manner to the thigh, as I recall distinctly having seen, while an interne in Bellevue Hospital in 1870, a similar extension applied to the thigh for fracture of the patella by Dr. Stephen Smith. However, in that instance the patient was kept in bed, and no effort was made to control the lower fragment by means of a plaster splint or by the influence of the extension employed in making traction upon the upper fragment. I have not, however, as yet seen or learned of the treatment of fracture of the patella by a method in any way contemplating the use of extending influence associated only with the limb itself, the introduction of a posterior stiffening support, and non-confinement of the patient in bed.

THE DISPOSAL OF SEWAGE.

BY D. BEVAN, M.D.,
INSTRUCTOR IN HYGIENE AND CLINICAL MICROSCOPY IN JEFFERSON MEDICAL COLLEGE; BACTERIOLOGIST TO ST. AGNES'S HOSPITAL.

THE question as to the disposal of human excrement has agitated the mind of man from time immemorial. The earliest authenticated record we have of laws regulating the disposal of excreta is in the injunction laid upon the Israelites to so fashion their spears that they might dig holes in the earth and therein bury their dejecta. The Israelites being at this time a nomadic people, and the country but sparsely settled, such a method was without serious objections. With the establishment of permanent camps and cities, however, the people were compelled to devise other means.

In the earlier ages, and also at the present time in remote places, privies built on the ground-level over shallow holes or barrels, etc., sunk in the ground were deemed sufficient. These muck-heaps were often situated in close proximity to dwellings and the sources of water-supply. The solid portion was seldom removed, but accumulated, and formed a vast pest-heap, which, when it was decided to clear it away, was quickly disposed of in the most convenient water-course, though occasionally it was used for fertilization. The liquid portion, containing noxious organic and inorganic substances in solution, percolated through the soil, polluting the source of water-supply and vitiating the air passing through the ground into the house. With the enlightenment of the people and renunciation of the abject servility imposed by political demagogues and hierarchies, science, deprived of right and destitute of prerogatives, was importuned to relieve the nation of its stink, to check and annihilate the filth-diseases rampant throughout the civilized world. Sanitary science, thus fostered and encouraged, responded nobly and has now discovered processes whereby sewage may be purified and utilized without seriously jeopardizing public health.

In this article only the discussion of the most important methods will be taken up. These include (1) the precipitating process; (2) the filtration process, and (3) irrigation.

The objective point in precipitating processes is the separation of the solid constituents from the liquid portion and rendering the effluent pure, or at least innocuous.

Two methods are practised to attain this result: (1) By simple subsidence, and (2) precipitation with chemicals.

By the first procedure the sewage is directed through wire screens into tanks provided with overflow tubes. The sewage remains in the tank for a time sufficient to separate the fluid from the solids. The effluent is drawn off through the overflow tubes and the sludge removed and burned or sold for fertilization. The liquid is allowed to flow into the most convenient water-course. As chemical analysis has demonstrated that this liquid is but little improved by subsidence, this process has been given up for a more efficient one: The effluent is passed through perforated drains from one to one and a half feet under the ground-surface and allowed to escape into the subsoil. This method is, however, applicable only for single houses and small communities.

Precipitation by chemical agents. By the admixture of certain chemicals the suspended and a considerable amount of the dissolved matter is precipitated. The sewage should be treated while in a fresh condition and the chemicals added before it is discharged into the receiving tanks or reservoir. These tanks are arranged in duplicate series, their number depending upon the amount of sewage to be treated.

The chemicals from which the best results have been obtained are lime, aluminium sulphate, and ferric sulphate, used separately or in combination. After precipitation, although the effluent is clarified, it is not innocuous, and to complete the purification it is expedient to combine the filtration with the precipitating process.

The filtration processes are effected by straining the sewage through substances having the faculty of arresting the solids and purifying the effluent. In some instances the sewage is simply strained through gravel or coarse sand. By this method the suspended particles are arrested, but the effluent is not purified. Carbon has been employed, but has proved unsatisfactory. Of all filtration processes, intermittent downward filtration through earth most completely purifies sewage. The degree of efficiency depends upon (1) the porosity of the soil, (2) the fall of the land. There should be one cubic yard for each eight gallons delivered in twenty-four hours. It is computed that one acre of ground will take up 100,000 gallons of sewage in twenty-four hours. To further facilitate the filtration of sewage, it should be delivered in pipes at least six feet under the surface. The filtration surface should be divided into four sections, and no one section should receive sewage for more than six consecutive hours. The surface of the plot should be ploughed in ridges on which vegetables are grown.

In England, irrigation, combined with either filtration or precipitation, has been pronounced the most efficient and profitable process for the utilization of sewage. The ground selected for the farm should be porous, light loamy soil. The farms are arranged in ridges along the tops of which run trenches carrying the sewage. The sewage is discharged at regular intervals, through series of sluiceways, into furrows. On the ridges are grown Italian rye, grass, peas, maize, cabbages, cereals, etc. The suspended organic matters are arrested in the soil and oxidized or resolved into harmless compounds by the organisms there present. The dissolved organic substances furnish pabulum for the growing vegetation.

This country, with its cities environed by extensive agricultural districts, affords the most happy and natural facilities for the employment of sewage.

A modification of the foregoing process might be adopted with profit to a municipality and the advantage of enriched lands and augmented crops to the agriculturist.

The sewage of the city of Philadelphia is disposed of in two ways: (1) By the sewers emptying

into the Delaware and Schuylkill Rivers, and (2) by being conveyed to the "Neck,"[1] where it is discharged upon the lowlands.

By the first process, our rivers (the sources of the city's water-supply) receive directly and undiluted the pestilential sewage of the city and the noisome refuse of the manufactories situated along their banks.

The rivers are thus practically converted into immense sewers, and the peculiar, delectable flavor of this mixture has conferred upon Philadelphia a most invidious distinction.

In the second method, the sewage is conveyed to the dumping-grounds in tank wagons, where it is transferred to sprinklers and promiscuously distributed in the furrows, over the vegetables, here, there and everywhere. The dumping-grounds ultimately become the most foul and noisome marshes conceivable. Not satisfied with begriming Nature's sweet face with the filthiest of filth, these philanthropic individuals turn their cattle into these muck-fields to pasture.

Though the effects of this latter method are not so widespread, its baneful influences are terribly obvious in the southern section of the city, and particularly in the southeastern section; for it is here that the milkman of the "Neck" carries a pail in one hand from which he dispenses elaborated garbage (so-called milk), tinctured with sewage, and in the other a bucket in which he collects the crude article. Is it surprising, then, that this method should be considered not less objectionable than the first?

The pail system adopted by Rochdale, Nottingham, Halifax, Manchester, Leeds, and Birmingham, deserves passing notice. The "by-laws" require (1) specially constructed closets, and (2) suitable pails.

The floor of the closet, made of some impermeable material, is raised several inches above the ground-level, with a slope of one-half inch to the foot toward the door. It is well ventilated by a six-inch shaft extending from beneath the seat to above the roof. The seats are hinged in order that the pails may be readily removed. The pails are made of wood and coated with creasote, or tar and galvanized iron. They should be round, with flanged tops and have a capacity not exceeding eight cubic feet. An airtight-fitting lid is provided to prevent nuisance in removal. In use they are placed in juxtaposition with the seat. Some of the cities mentioned have a second pail for the reception of ashes, house-refuse, etc.

Feces, having been discharged into the pail, are sprinkled over with finely sifted ashes or soil, which act as deodorants.

[1] The territory in the county of Philadelphia lying between the Delaware and Schuylkill Rivers and south of Snyder avenue.

Where the pail system is in operation the sewage is burned in furnaces, or by the addition of finely sifted ashes and lime converted into fertilizing material.

We think it not inopportune to conclude by mentioning the method adopted in London. The sewage is conducted by the main sewers to Barking and Crossness. Large works have been completed at Barking, and similar works are in process of construction at Crossness, for separating the grosser element. Before the sewage enters the works it is strained through iron cages which retain the larger bodies. This, amounting in one week to seventy tons, is incinerated in a Hoffman furnace. The liquid, having in suspension the finer particles and a considerable quantity of dissolved organic matter, is directed into large tanks for subsidence, which is facilitated by the addition of lime, thirty-seven grains, and iron sulphate, fourteen grains, to each gallon of sewage. In this manner twenty thousand tons are precipitated in one week. The sludge is forced by powerful pumps into tanks on board ships expressly constructed for the purpose. The ships, having a capacity of one thousand tons, convey the sludge to sea, where it is discharged. The effluent, containing but two grains of solid per gallon, disembogues into the Thames.

The abandonment of this process is but a question of time, for it is manifest that such enormous quantities of sludge will eventually so silt up the estuary of the Thames as to seriously interfere with commerce; and, indeed, may prove a grave source of pollution.

CLINICAL MEMORANDA.

A CASE OF PURPURA HEMORRHAGICA.

BY WM. R EARECKSON, M.D.,
OF ELK RIDGE, MD.

ON Sunday, July 3d, I was called to see James F., Jr., nine months old, who was suffering from an attack of cholera infantum. His previous health had been good. His father is a robust man, while his mother looks tuberculous, although no pulmonary trouble can be detected. There was one other child, an extremely plump and healthy sister. The grandparents are all living, and perfectly well, except the paternal grandfather, the nature of whose trouble I could not ascertain. The cholera infantum yielded readily to treatment, and in about ten days was completely cured. Directions were given that sterilized milk be used and the child be kept in the open air.

On July 20th, I was again called to see the patient, who was said to have broken out with a rash. I found a deep scarlet flush on the left side of the face, covering the forehead to the middle line, extending down the nose, lips, and chin to a point about midway between the mental prominence and thyroid cartilage. Thence the line of redness followed closely the position of the digastric

muscle, and up in front of the ear along the course of the external carotid and temporal arteries.

There was no distinct rash, but simply a diffused redness, such as is sometimes seen from vasomotor disturbance.

The right side of the face was normal in appearance. I explained this localized flush by supposing that the left side of the face had been exposed to the glare of the sun, while the child lay in its cradle, the weather at the time being intensely hot. The hands and limbs, however, were normal, although equally exposed. The axillary temperature was 99.8° F., the pulse 112, and the child cried if lifted about, as though there was hyperesthesia of the skin. There was no sore-throat or other symptom to account for the condition. I ordered a simple mixture containing liquor ammonii acetatis, ℥xv to ʒj, every three hours. When I called on the following morning (July 21st) I found that the left cheek was almost normal in color, but presenting several little spots of eruption such as seen in measles, while the right cheek was almost as flushed as the left had been, the redness, however, not being so decidedly circumscribed.

The treatment was continued. The kidneys and bowels acted normally, and except for this flush and slight elevation of temperature I could detect nothing abnormal. The child, however, was fretful, and cried if lifted from his cradle. I ordered plenty of nourishment, fresh air, and stimulants at regular intervals.

On July 22d, I found very little flush, but on both cheeks there were a few spots of eruption similar in size to those of measles. These were confined exclusively to the face, but the wrists and legs, from about two inches above the knees, were rather more deeply colored than normally. The bowels moved three times, the evacuations being thin, but normal in color.

The condition was so much improved that I did not visit the child again until the morning of July 26th. I found the temperature slightly elevated, and the pulse rapid and weak.

In the afternoon, at about 5 P.M. I was stopped, while passing the house, and asked to see the child again, as it was bleeding. Its mother told me that at about 10 A.M. she noticed a purple spot, about the size of a flaxseed, on the right cheek, just below the angle of the mouth, which gradually grew to about the size of a five-cent piece. In turning over in bed, the child scratched this spot on the pillow. From that time until about 4 P.M. it bled constantly. The bleeding was stopped, finally, by means of hot water and pressure.

On close examination, I found about one hundred small red specks, about the size of pin-heads, scattered over the face and neck, and a few on the abdomen and thighs. On the legs, feet, wrists, and hands one could scarcely see any healthy skin, on account of the numerous red spots.

The trouble was then recognized to be purpura hemorrhagica or morbus maculosus of Werlhoff, and the parents were informed of the possible fatality of the condition. Aromatic sulphuric acid was ordered, together with a generous amount of diet and stimulant.

That night epistaxis began and continued, until, after milder astringents were found useless, I gave a spray containing subsulphate of iron and increased the amount of acid.

The temperature then was 100.4° F., and the pulse 122. The child was fretful and cried when disturbed. A slight enlargement of the spleen was noticed and slight tenderness was manifest on pressure.

During the day of July 25th, the child vomited a moderate quantity of dark blood, and the acts of vomiting started epistaxis again. An emulsion containing oleum terebinthinæ was ordered.

The pulse was markedly thready and weak, while the temperature remained about as previously. Epistaxis was controlled by nothing except the spray of Monsel's solution.

From July 29th to 31st, inclusive, the amount of blood vomited daily increased, as did also the frequency of vomiting. Epistaxis was, however, not quite so severe. The petechiæ increased in number, especially upon the abdomen, thighs and upper arms, but did not show any tendency to increase in size. The urine became deeply colored and stained the napkins a reddish-yellow, but the quantity was apparently normal. The stools were liquid and contained no blood. The spleen was perceptibly enlarged and slightly tender. Not being satisfied with the effect of the turpentine, although the quantity was carefully increased daily, the fluid extract of ergot was ordered in fairly large doses. The pulse-rate ranged from 120 to 132, while the temperature was from 99.6° to 100.2° F.

From August 1st to 5th, the acts of vomiting were less frequent, and the amount of blood diminished. Epistaxis was very slight. No blood was seen in the stools, but the urine still stained the napkins. On August 2d, large blisters containing serum were first noticed upon the right cheek where the cutaneous bleeding occurred, and by the next day the same condition was present on the dorsum of the feet and hands. By this time the skin was very pallid, especially on the face. Several times during these five days the child showed signs of brain-irritation—threw its head back, and rolled it about on the pillow. The ergot was continued.

On the morning of August 5th, the child was apparently stronger. The hemorrhage from the stomach was very slight, and only a slight, yellowish discharge from the nose was noticed.

Stimulants and nourishment were given regularly. Ergot was continued. That night, the father called me up, saying that the little sufferer was dying. Hemorrhage from the stomach and nose had started afresh; there were moist râles all over both lungs, and respiration was accelerated. The skin was peeling from the child's face, hands, and feet. The whole skin from the top of the right foot peeled off in one large piece. Increased doses of ergot, whiskey and milk were ordered. Ice was also given, while artificial heat was supplied by means of hot bottles.

On August 6th, the whole body was extremely pale. The spleen was enlarged. The bowels were moved only three times within the preceding twenty-four hours; the stools were watery. The hemorrhage diminished. The urine was about normal in quantity, but stained the napkins. The pulse was 142 per minute, and quite compressible. The temperature was 99° in the morning, and 98.8° F. in the afternoon. The weather was extremely warm and the child was much prostrated.

From August 7th, there was no further hemorrhage.

The temperature was 98°; the pulse 146, and very weak. The extremities were cool. Stimulating measures were kept up, and hot bottles were used.

On August 8th and 9th the child was apparently stronger and noticed those about it. The urine stained the napkins less than formerly. The pulse was from 150 to 158, the temperature 98°. The parents were apprised of the approaching end.

On August 10th, the moist râles continued. Respiration was rapid and shallow. The temperature was 100.6°, the pulse 154. The baby was apparently unconscious. The extremities were cold and marble-white, except for the small, brownish, hemorrhagic specks. Hot bottles and stimulants were used more often. The head was repeatedly thrown back and rolled about on the pillow. During the middle of the day this condition gradually gave way to coma, and at 3 P.M. death came.

The mother has since been delivered of a female child which had considerable umbilical hemorrhage.

This case was intetesting to me on account of (1) the long prodromic period, during which no decided symptoms appeared; (2) the cutaneous hemorrhage and very marked desquamation at the site of greatest cutaneous hemorrhage; (3) the diversity of marked symptoms after the full development of the disease. consisting of hemorrhage from not only the nose and stomach, but probably also from the bronchial mucous membrane and into the brain.

No autopsy was permitted.

TO PREVENT LACERATIONS OF THE PERINEUM BY THE SHOULDER.

BY ALICE MACLEAN ROSS, M.D.,
OF SWATOW, CHINA.

So much has been said regarding ruptured perineum that I feel reluctant about bringing the subject again forward, but in the matter of prevention, I feel sure that not enough has been said in regard to tearing by the shoulder. After great care has been taken, and every precaution exercised to prevent laceration by the head, and one is congratulating himself upon having managed matters so that the patient has escaped with perhaps nothing but a little nick in the fourchette, a final terrific pain drives the lower shoulder straight through the perineal body, and perhaps makes a rupture clear through into the rectum. An internal parting of the mucous membrane of the vagina, or a slight tear, is often thus converted into an extensive laceration. The matter of preventing tears is certainly not complete without regarding the shoulder as a pretty frequent cause and directing some attention toward preventing the continuity of the perineal body being dissolved by it. If the head has been successfully delivered, it is well to look out for the shoulder.

The indications to be met in accomplishing the safe birth of the shoulders are these:

1. Direct the body upward into the axis of the outlet.
2. Lessen the transverse diameter of the body of the child.
3. Cause the exit of the body to take place slowly and gently.

When the mother is lying in the dorsal position the weight of the child's head, after it has emerged from the vagina, tends to drag the body downward and outward through the perineum, instead of outward, upward, and past it, as it should go. So the head ought to be supported, and the body directed upward in its outward passage. The transverse diameter of the body of the child may be easily lessened to a considerable extent by pressing upon the perineum and driving the upper shoulder against the pubic bone, thus doubling both shoulders over the chest.

The slow exit of the body may be brought about by pressing upon the head and retarding its motion during the pain that expels the body. But the pain that brings the body is usually a pretty violent one, and the movements of the neck prevent perfect control being obtained of the child, and notwithstanding all these precautionary measures the slippery parts are likely to ge from under the hand, and the damage is done in spite of all efforts. After delivering the head safely, I have been disappointed in the most aggravating way by finding that the shoulder has caused a tear, and have recently dropped into performing a maneuver which might be called the "cork and bottle" maneuver, as its motions are exactly like those undertaken in extracting a cork from a bottle with a corkscrew. I have found it exceedingly useful in extracting the body, after delivering the head with forceps, and in delivering the shoulders when laceration by them seems imminent, either on account of a rigid perineum, a partial parting tear of the fourchette, or the appearance of bright blood on the child's face, denoting an internal parting of the mucous membrane. It fulfils all the indications for safe delivery, and in my hands has been successful in enabling me to avoid tears by the shoulders. The maneuver is carried out as follows: First grasp the child's head by hooking the first and second fingers around the neck and allowing the chin to rest in the palm of the hand (the presentation being normal). Perfect control of both body and head is gained in this way and the child's advance can be either retarded or accelerated at will. With the other hand grasp the bulging perineum and make firm pressure upward, pressing the upper shoulder against the pubic bone, and lessening the transverse diameter of the child's chest. Then delivery may be safely accomplished by pulling upward upon the head in the direction of the outlet, gently and steadily. The whole act may be accomplished in a moment, the usual interval which intervenes between delivery of the head and body allowing ample time for its performance.

A CASE ILLUSTRATING THE TREATMENT OF PAINFUL PROLAPSED OVARIES IN YOUNG GIRLS.[1]

BY G. BETTON MASSEY, M.D.,
OF PHILADELPHIA.

The case that I herewith report is illustrative of the treatment of painful prolapsed ovaries in young girls. The previous history of the case will also suggest a possible way in which vaginal ovaries can become prolapsed and painful without traumatism.

[1] Reported at a meeting of the Philadelphia Obstetrical Society, December 1, 1892.

The patient is a young lady of a sensitive literary family, with an introspective bent. She menstruated early, and, like many young girls, had painful periods. She was ill-developed physically, and the periods were irregular. With the ultra-mechanical ideas of the present, her physician sent her to a surgeon for treatment. The surgeon is said to have diagnosticated endometritis and uterine prolapse of moderate degree, and he inserted a pessary. Therein, I am sure, lies the cause of the subsequent prolapse and hyperesthesia of the ovary.

She was sent home, some distance from the office of the surgeon, but the pain was not relieved. Before the pessary had been worn long it was removed by the attending physician, but not before there was aggravation of the preëxisting condition, which I now suppose was one of those minor endometrial catarrhs so common in patients of the class to which the girl belongs. The case went from bad to worse, and there were numerous consultations with physicians and surgeons, and removal of the ovaries and tubes was advised by several.

When seen by me, three years after the inception of the trouble, she was twenty-one years old. The uterus was in a condition of catarrhal inflammation, enlarged and tender. The ovaries (particularly the left) were prolapsed and very tender, although not enlarged. The position and the painful condition of the ovary were, I conceive, the factors that had led so many surgeons to advise the unsexing of this young lady, and according to accepted teachings this advice was warranted. I looked on the case, however, as primarily one of uterine disease, having had added to it the ovarian trouble and the general neurasthenia from which she suffered.

In brief, this patient was placed on electric treatment and rest for the neurasthenia, and was subjected to vaginal treatment by the galvanic current with a covered positive electrode. Great amelioration of the tenderness of the left ovary followed. Up to this time, a period of some weeks, the uterus had not been explored, but owing to the copious catarrhal discharge I thought it well to pass a flexible aseptic sound, which may be done with less danger of injury than if the rigid instrument be used. The uterus was found to be over three inches in depth, showing a source of trouble beyond the ovarian displacement. She was then put on the direct treatment for the endometrial inflammation, intra-uterine galvanic and faradic currents, care being taken not to bruise the sensitive tissues outside of the uterus by any undue movements. From the first internal treatment improvement was noted, the continuous pain in the left ovarian region being somewhat relieved. The following period was much easier, and she went on to a rapid recovery after a treatment of two or three months. She was discharged cured from my sanatorium five months ago, and recent advices state that she is entirely well, natural in her periods, and gaining flesh.

It may be asked: What became of the ovary that was destined to be removed? It still remains somewhat lower than its fellow, but floating freely; and I think that the slight deviation in position will not cause any more trouble than a like freedom of movement in any of the internal organs.

IRRITATION FROM THE LOCAL USE OF IODOFORM.

BY J. ABBOTT CANTRELL, M.D.,
ADJUNCT PROFESSOR OF DERMATOLOGY IN THE PHILADELPHIA POLYCLINIC; DERMATOLOGIST TO THE PHILADELPHIA HOSPITAL, AND TO ST. AGNES'S HOSPITAL.

THE pain and discomfort following the application of iodoform to raw surfaces has caused me to abandon the use of this agent in this way. I prefer to use one of the blander and less irritating iodine-compounds that have lately been brought forward, such as iodol or aristol. I have lately noticed reports in some of our journals of marked irritating effects from the local employment of iodoform.

Within the past few weeks I have seen several cases in which the effects of this drug have been actually caustic. The two herewith reported are striking examples.

CASE I.—J. M., a male, thirty-three years old, had had an abscess on the outer side of the left leg, about two inches above the malleolus, which was incised and dusted with iodoform and bandaged.

In about five days he presented himself to me with a most painful leg, which upon examination showed an area of ulceration about the size of a silver quarter-dollar at the site of the recently-opened abscess, and surrounding this for a radius of quite three inches was a decidedly irritated and inflamed surface, covered with numerous minute ulcerations, each one of which in itself resembling an ulcer and discharging a small quantity of pus. My first thought was of traumatic erysipelas, when upon careful questioning the facts related were elicited. The temperature at this time was 98.8°.

The man could hardly walk, and the little he did was exceedingly painful.

He was ordered a solution of ichthyol in water (ʒij to fʒiv); to be followed in a few days by an ointment containing hydrargyri chloridum mite, gr. xv; unguentum zinci oxidi, ʒj, and recovery speedily ensued.

CASE II.—L. B., a male, thirty-two years old, presented himself with a painful patch about four inches in diameter directly over the left patella, stating that he had fallen and bruised the parts, causing an abrasion of the skin. He was advised by his family to dust the parts with iodoform, and in addition he covered them with a zinc ointment. In about three days his knee was greatly swollen and highly inflamed, the whole patch being covered with a number of minute ulcerations, similar to those mentioned in the other case. The man presented himself after a severe drenching in the rain, and the appearances were more decidely erysipelatous than in the first case. There was no elevation of temperature.

The man was given an ichthyol lotion, followed in a few days by the following: Picis liquid., sulphuris sublimat., āā ʒss; ungt. zinci oxidi, ʒj, which was applied twice a day. In about two days he was almost well.

Of course, the report of these two cases is not evidence of the absolute inutility of iodoform, but it indicates that we cannot be too careful in its use.

For myself I shall not use it as long as there are other remedies that may produce as good results without unpleasant irritation. I believe that iodol and aristol are the iodine-compounds upon which we can safely depend.

Iodoform has proved itself of great value in antiseptic surgery, but its irritating qualities must not be overlooked.

LARGE DOSES OF NITRO-GLYCERIN.

BY G. A. HIMMELSBACH, M.D.,
LATE RESIDENT PHYSICIAN, GENERAL HOSPITAL, BUFFALO, N. Y.

THE following report is simply intended to show to what extent a drug-tolerance can be established.

A. L. P., fifty years old, a miller, entered the Buffalo General Hospital February 20, 1892. Until seven years ago he was a strong, vigorous man, when he was seized with sharp pain in the precordial region, lasting but a few seconds. Similar attacks occurred several times during the succeeding two years. The paroxyms then came on at shorter intervals and with increased severity. The case was diagnosticated as one of angina pectoris, and nitro-glycerin was given; gr. $\frac{1}{100}$ was at first found to be too large, so that gr. $\frac{1}{400}$ was given. This would lessen the severity of the attack very appreciably, and for a long time the dose was sufficiently large to bring about relief. For five years the attacks continued, and for their relief the man depended solely upon nitro-glycerin, the dosage of course keeping pace with the increased frequency and severity of the paroxysms.

When I first saw the patient he was having attacks at intervals of from twenty minutes to two hours, and each one seemed to be more intense than the preceding one; each lasted from five to thirty seconds or more. Several times during severe paroxysms a pronounced systolic murmur could be distinctly heard fully four feet from the patient, for a period of from fifteen to thirty seconds, which would gradually become fainter until it could only be heard by auscultation.

During these seven years of suffering the patient had learned to anticipate the paroxysms some two minutes in advance of their onset, when he would resort to nitro-glycerin, which would lessen or dispel the attack like "magic."

The patient informed me that he was in the habit of taking no less than from six to ten gr. $\frac{1}{100}$ triturates, *ad libitum*, as a prophylactic dose. At times even this amount was not sufficient, from fifteen to twenty being required. I finally substituted gr. $\frac{1}{50}$ triturates and kept strict account of the number. The total amount taken ranged from eighty to one hundred and ten each day. This gradually increased until he took a total of one hundred and twenty-five gr. $\frac{1}{50}$ triturates in twenty-two hours; then for the eight succeeding days he took exactly *one thousand* gr. $\frac{1}{50}$ triturates, or a total of gr. xx. At about this time Dr. Stockton suggested the use of oxygen. Accordingly, nitrous oxide and oxygen, in the proportion of 1 to 4, were administered at regular intervals and at the approach of a paroxysm. This measure was the most effectual of any yet tried. By this means the glonoin was reduced to a minimum and the patient suffered comparatively little pain. He continued in this condition for one week, when he decided to go home, having acquired the technique of administering the gas. Brandy ℥ij, several times daily, seemed to be the only means of inducing restful sleep.

Potassium iodide was given, but subsequently withdrawn, on account of diarrhea. Many other remedies strongly recommended for angina pectoris were tried, but proved of little efficacy.

The patient died a week or so after reaching home. No autopsy was permitted.

NEW DEVICES.

COMBINED TONSILLOTOME AND UVULATOME.[1]

BY JOHN L. ANCRUM, M.D.,
OF CHARLESTON, S. C

HAVING been long convinced that many cases of post-nasal disease were aggravated, if not primarily caused by scrofulous or other chronic hypertrophy of the tonsils, it has uniformly been my practice for many years to excise them promptly, whenever hypertrophy existed to such degree as to be plainly evident, or in even a minor degree to interfere with the easy and natural breathing of the subject.

FIG. 1.

Early operation in these cases eliminates the only, and, I may say, much magnified danger from hemorrhage, inasmuch as the bloodvessels of the tonsil in its normal condition are largely venous, and the arterial vessels very small and limited. We thus anticipate their possible enlargement, which, except in constitutional bleeders, is a minor consideration, as they never enlarge to any appreciable or dangerous extent.

While the numerous tonsillotomes now in use are ingenious in construction, and fairly efficient, they all retain the two objectionable features in the compulsory use of both hands in manipulating them, and the additional difficulty in the short fulcrum and long leverage of keeping them with certainty in any fixed position when the knife is being drawn. This has induced me to combine some of the several original designs into a single-handed instrument, uniting the qualities of a tonsillotome and uvulatome in one, as nearly perfect as it is possible to be, thanks to the skill and workmanship of Messrs. Tiemann & Co., of New York.

As will be seen by reference to the drawing (Fig. 1) the instrument has a concealed spring within the rubber handle; the knife, when brought into position for operation by pressure upon the bulb, closes the spring down and is held by an automatic catch. The tonsil being surrounded by the loop, the dart (which is intended to prevent the excised portion from falling into the larynx) is quickly pushed down by the thumb-piece, and, upon reaching the proper point releases the catch, when the knife flies upward instantaneously, and

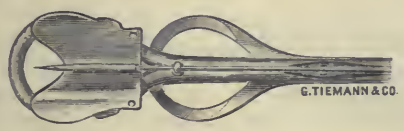
[1] Presented to the South Carolina Medical Society.

painlessly removes the tonsil, the patient scarcely realizing that the operation is done.

By the local application of a solution of cocaine the excision is so entirely painless that, practically, nervous persons (who furnish the most numerous subjects) can be deceived by the idea that no cutting has been done, and the opposite tonsil can be removed under the deception, when, otherwise, as often happens on the use of other instruments, it is not easy, or even possible, to persuade them to have the operation repeated.

By a simple device the same instrument is converted into a uvulatome of equal efficiency (Fig. 2); a light

FIG. 2.



metal disc is slid upon the dart; the edematous or elongated uvula is allowed to fall into the opening, and the dart, being pressed forward, carries the disc into the uvula before it until sufficient resistance is offered, when it stops and holds the uvula steadily while the dart passes onward through the uvula and releases the knife as before, and instantaneously excises as much or as little as the surgeon chooses to have passed the dart through.

ALUMINUM WIRE PESSARIES. (WOOL-WRAPPED).

BY J. M. KEATING, M.D.,
OF COLORADO SPRINGS.

WHATEVER may be the opinion of some extreme gynecologists, probably the pessary, in some form or another, will continue to be used with success by the majority of medical practitioners who see much of the diseases of women. Those who are looking over medical literature every week, of course, note the opinions expressed by many extremists, and it is possibly well that such views should be made public, in order that the majority may be able to steer clear of them—in the middle of the stream. The objectionable features of the pessary and its application, in the hands of those who are ignorant or careless, have led many to condemn it entirely, and all sorts of surgical procedures, which are not applicable to the majority of patients, have been suggested to take its place. A well-applied pessary, which is constantly looked after, is a great comfort, and, in fact, a curative agent in a large proportion of cases; but one would no more think of putting a splint on a fractured or lame leg and forgetting it, than to introduce a pessary and forget it. It is not simply intended as a support, or an ornament, but it has an actual curative value in proportion to the amount of brains that is used in its adaptation.

The ordinary hard-rubbber pessary has the same disadvantages that a ready-made suit of clothes or a ready-made shoe has, *viz.*, that it rarely suits the case. Then, even if it does suit, at some time, within a few days or weeks, its shape has to be changed, to conform to the new state of affairs. This is a very simple matter when there are instrument-makers close at hand, and, indeed, with an alcohol lamp or boiling water it is not so very difficult anywhere. Nevertheless, I have often been puzzled to know how to arrange the pessary so as to get all of the benefit from it, and recently the thought occurred to me, which I think may be of use to my fellow-practitioners, to have rings of various sizes made of *aluminium wire*, stiff enough to be of service and yet not too stiff to be difficult to shape.

The wire that I use is about the size of a lead in an ordinary lead-pencil. The rings can be made very easily by oneself with an ordinary pair of strong pincers. The sizes that I have found available are two and a half and three inches in diameter. These are wrapped with wool, so as to be about the thickness of one's little finger, and have a silk ligature tied at one end, and are left hanging as in the case of an ordinary tampon. This is a tell-tale which shows that the instrument is *in situ*. These wool-wrapped pessaries can now be shaped into any form and will retain their position. If they are soaked in a solution of four to one thousand mercuric chloride and then dried, they are ready for use. When introduced into the vagina, they can be very easily shaped by placing two fingers in the opposite way and pulling and pressing as desired. After the pessary has been subjected to the sublimate solution and dried, before placing it I usually soak the wool with the ordinary solution made by dissolving one of Seiler's antiseptic tablets in water. This wool, so subjected, I find can easily remain four days in a case in which there is some leucorrhea. If there is very little vaginal discharge, I think we could safely leave one of these pessaries in position a week. In using tampons I invariably apply them in my office and pack the uterus to get it into position; I use these pessaries in the same way. I then request the patient to return at the end of a stated time, and I withdraw the packing myself, thoroughly cleanse the parts, and introduce another. By placing the pessary in the flame, of course the wool is burned off, and the wire is ready to be used over again. The pessaries are very easily made by oneself; but if one does not care for the trouble, they can be had of E. A. Yarnall Co., of Philadelphia, who have made them up for me. I may say that I always use wool at the present day instead of cotton, as it is elastic, and, in fact, is the only thing that is of any use; it needs thorough greasing before it is introduced, as otherwise it is likely to irritate.

A NEW INSTRUMENT FOR THE TREATMENT OF URETHRITIS.

BY J. W. WILLIAMS, A.M., M.D.,
OF PATERSON, N. J.

IN the treatment of urethritis, particularly in the chronic stages of the disease, the beneficial effects of dilatation by sounds is well known, both in hastening the cure of the inflammation, and, what is even more important, favoring the absorption of those transient stenoses of the canal, which, if left to themselves, might become true strictures.

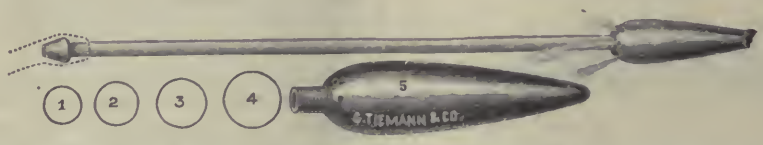
Neither is there any doubt as to the value of thorough irrigation of the urethra with warm water, or a solution adapted to the needs of the case.

In order to carry out these two indications conve-

niently and thoroughly I have devised the instrument here illustrated, made by Tiemann & Co., of New York:

The instrument consists of a straight metal tube, six inches long, and fourteen (French scale) in caliber. At one extremity is an enlargement, over which a rubber tube may be fitted to attach it to a syringe. At the other extremity is a "female" screw for attaching the heads of the instrument. These heads are the important and characteristic feature of the instrument.

They are practically short sounds of the shape shown in the cut. They are five in number, ranging in size from eighteen to twenty-nine, French scale. Each head is an inch and a half in length, and provided with a short



"male" screw for attaching it to the handle. The base of the head is bored for a short distance, so as to be continuous with the bore of the handle. Communicating with the interior of the head and opening around its base are four apertures, directed backward, so as to give a reflux current when fluid is passed through the tube.

The manner of using the instrument is obvious and needs no explanation. I might state, however, that, in addition to plain warm water, I have found the following solutions particularly useful in treatment:

1. A 1:10,000 solution of potassium permanganate.
2. A solution of a teaspoonful of common table salt in a quart of warm water.
3. Thiersch's solution.

Use a fountain syringe and plenty of the solution. The instrument is not to be used until the first, acute stage of the disease has passed, during that time injection of warm water in the usual way with a blunt-nozzled syringe being practised. For irrigation of the deeper portions of the urethra I prefer simply a small-sized soft-rubber catheter—that is, when such a procedure becomes necessary.

The advantages I claim for this instrument (which I have termed an "Irrigating Sound") over other more elaborate forms are the small amount of pain, if any, caused by its introduction; the free flow of the fluid used; its simplicity; and the thoroughness with which it carries out its two objects—dilatation and irrigation. I have had good results from its use, and would recommend it to the profession.

MEDICAL PROGRESS.

Successful Removal of a Tumor of the Left Frontal Lobe.—At a recent meeting of the New York Neurological Society, DR. ARTHUR BOOTH reported the case of an unmarried male, twenty-four years old, who had had hip-joint trouble from childhood, but for eighteen months had had epileptic attacks, general in character. There was no history of an attack of hemi-spasm, or any spasm limited to a single group of muscles, although it was thought that the jerking was most marked in the right arm. In the last seizure, six months before coming under observation, the man had fallen, striking the chin and left side of the head quite severely. There was no other history of injury. Shortly after this, a swelling on the left temple was noticed for the first time, the patient himself, however, stating that it had been there before the fall. At about the same time marked failure of vision was observed. The patient was also troubled by a turning in of the left eye. There was no history of hemianopsia. For a month the man had what he designated as fainting spells, in which there were no convulsive movements. For a year he had had a good deal of headache of a severe character, chiefly referred to the forehead, extending through the temples, and often radiating back as far as the occiput. There had never been vomiting. Memory had failed much during the year, so that it became difficult to recall recent events and the names of those with whom the man was well acquainted. There had been a marked change in the man's manner; he had become dull and disinclined to talk. Syphilis was denied. A family history of pulmonary tuberculosis was wanting. The man's manner was quiet; his face rather expressionless. Speech was slow and somewhat uncertain, though there was no aphasia. The tongue was protruded straight. There was no decided paresis of the face, but there was a slight loss of expression on the right side. There was paresis of the right external rectus. The pupils were widely dilated; there was no reaction to light or in accommodation. Vision was reduced in both eyes, in the greater degree upon the left. There was bilateral optic neuritis, with numerous small retinal hemorrhages. The station was fairly good with eyes closed; there was no ataxia; the knee-jerks were absent, even with reinforcement. There was no anesthesia or analgesia. The sense of taste was normal. The sense of smell was deficient on the left side. On the left temple, just back of the external angular process of the frontal bone, there was quite a prominent swelling, oval in shape, somewhat tender, pressure on which caused pain, radiating through the head as far back as the occiput. Deep pressure at the base of the tumor disclosed an absence of bone at that point.

The symptoms were considered sufficient to warrant a diagnosis of an intra-cranial tumor in the anterior fossa, in the left frontal lobe, and operation was decided upon. When the tumor was exposed it was found to be covered by a tough, soft, red membrane, containing cheesy material, which was removed with a spoon. The circular opening in the bone was found to be one inch in diameter, and the dura mater enclosed the opening. The opening in the bone was enlarged and the dura mater separated from the roof of the orbit, where the tumor was adherent and had caused absorption of the bone. The dura mater was now opened and the tumor enucleated with the finger. There was no shock following the operation; the patient slept well during the night, and the next day talked as well as before the operation. A week later, examination of the eyes showed extensive hemorrhages occupying the entire right retina and two-thirds of the left. There was no perception of light.

After an interval of ten days sight was suddenly recovered to some extent in the left eye. Six days later the patient had a general epileptic attack, and after this again became blind, and remained so. A later examination of the eyes revealed choked disc in the atrophic stage in both eyes.

The Relation of Pseudo-diphtheric Angina to Diphtheria.—BOOKER (*Bulletin of the Johns Hopkins Hospital*, iii, 26, p. 109) records the results of a bacteriologic study of eleven cases of scarlatina, with pseudo-membranous angina; four cases of scarlatina, with redness of the throat, but without pseudo-membrane; one case of pseudo-membranous angina, similar to that of the cases of scarlatina, but without exanthem; two cases of measles, followed by membranous laryngitis, but without visible deposit in the throat; one case of measles, followed by a pseudo-membranous affection of the throat and eyelids; and three of ordinary follicular tonsillitis, without resemblance to either scarlatina or diphtheria. He concludes that the pseudo-membranous affections of the throat that sometimes occur secondarily to scarlatina, measles, and, perhaps, other infectious diseases, often present the clinical features of diphtheria, from which, however, they differ in nature and etiology. The clinical features are not always sufficiently distinctive to differentiate these affections the one from the other. The anatomic changes induced by the activity of the bacillus of diphtheria appear to be characteristic, and unlike those present in the pseudo-diphtheritic processes. Excepting the false membrane, the anatomic changes found in diphtheria are dependent not upon the direct action of the bacilli, but upon a toxic substance to which they give rise. These changes are characterized especially by focal necrosis of tissues, with a peculiar splitting of the nuclei of the cells. The anatomic changes that attend the pseudo-membranous angina of scarlatina are accompanied with an invasion of streptococci, with suppurative processes. The etiologic factor furnishes a certain criterion for the differentiation of diphtheric and pseudo-diphtheric processes, but the diagnosis is, nevertheless, sometimes difficult. Measles and scarlatina render the tissues especially vulnerable to the bacillus of diphtheria. The constant presence of streptococci in pseudo-diphtheric processes is suggestive of an etiologic connection. The streptococci have not been differentiated, and it is presumed that different forms may occur. The relation of streptococci-infection to scarlatinal pseudo-membranous angina has no bearing upon the specific etiology of scarlatina.

Unique Fracture of the Pelvis.—NEUGEBAUER (*Centralbl. f. Gynäkologie*, 1892, No. 47, p. 913) reports the case of a strong, robust woman, twenty years old, who had been married three years, and had borne three children. Fourteen weeks after the birth of the last child, while out riding, the horses became frightened. In the hope of saving her child the mother threw it from her, but in the act lost her balance, and, falling between the horses, was run over by two of the wheels. A considerable time elapsed before professional aid could be brought; and the exact extent of the mother's injuries could not be learned. The child was killed. The woman convalesced after a stay of six weeks in bed. No information could be obtained concerning hemorrhage from the bladder, bowel, or vagina, and fever and suppuration. The woman only recalled that she at first suffered from severe pains, and for four weeks was entirely unable to move in bed, and passed urine and feces involuntarily. Walking was at first difficult, but gradually improved. Menstruation occurred a week after the accident, but was subsequently absent, the woman becoming pregnant. Examined in the third month of pregnancy, the gait was found to be pretty steady; the upper part of the body was held unusually erect; the pelvic obliquity was diminished; the pelvis was funnel-shaped. Vaginal examination disclosed the existence of a fracture of the horizontal and oblique branches of both pubic bones, with considerable separation of the fragments upon the left and union by callus upon the right. The fragments of bone to the left of the symphysis could be seen and felt to alternately rise and fall when the woman walked or raised her legs. Although the sacro-iliac articulations could not be examined, it is thought that they must have been injured, thus allowing of increased mobility.

Puerperal Neuritis.—MÖBIUS (*Münchener medicin. Wochenschr.*, 1892, No. 45, p. 799) has reported the case of a woman, twenty-nine years old, in which, two days after arising from bed, three weeks after the birth of a child, a sense of painful cramp appeared in the calf of the left leg. This kept the patient abed for three weeks, at the end of which time some enfeeblement of movement in the forearms manifested itself. A few days later there was complaint of pain in the scapular regions, which lasted for a week. Then in the ninth week, peculiar sensations in the right forearm were perceived; and the act of writing could not be performed, because the thumb failed to firmly grasp the pen. The flexor longus pollicis was wasted and presented reactions of degeneration. Electric treatment was followed by little improvement.

In a second case, a woman, fifty-five years old, complained of pain at the right elbow, which readily yielded to ordinary measures. Examination, however, disclosed the existence of atrophy of the ulnar and thenar muscles that had been present for thirteen years, following shortly after a labor. Motility was not materially impaired and the electric reactions were preserved.

Both cases are considered to be instances of neuritis of puerperal origin.

Resection of a Ureter.—KÜSTER (*Archiv f. klin. Chir.*, 1892, xliv, 4, p. 850) has reported the case of a boy, eleven years old, whose parents had for a long time noticed tumefaction of the abdomen, which examination disclosed to be dependent upon the existence of a left-sided hydronephrosis. An incision was made in the loin and a pelvic fistula established. It became evident that the right kidney was wanting. The lad recovered speedily from the operation, the fistula persisting, and no urine passing through the bladder. Some two years later, the fistulous opening was enlarged, when it was found that the ureter below the artificial opening in it was obstructed by an impermeable stricture. The ureter was cut through just below the stricture and also at its entrance into the pelvis. The lower portion was freed

and brought up into the capsule of the kidney, where it was sutured, the upper extremity being slit vertically, so as to form a funnel-shaped receptacle. On the day after the operation urine began to be passed by the bladder. The fistulous opening was finally closed by freshening its surfaces and introducing a series of graduated sutures. Recovery was eventually complete.

The Position of the Tongue in Peripheral Palsy of the Facial Nerve.—HITZIG (*Berliner klin. Wochenschr.*, 1892, No. 50, p. 1270) points out the disparity in the views of various authorities as to the position of the tongue in cases of peripheral palsy of the facial nerve. Some maintain that there is only an apparent deviation; while some describe a deviation to one side, and others a deviation to the opposite side. In some cases there have, doubtless, been mistakes in observation. In mild cases of peripheral palsy there is no deviation at all; while in the severe cases it is the rule for the tongue to be thrust out toward the unparalyzed side. This, however, is not the result of any palsy, but of a spontaneous tendency on the part of the tongue to avoid the angles of the mouth, so that it finds its way to the middle of the oral orifice. In proof of this fact the organ will be seen to follow the paralyzed side of the mouth if this be drawn with the finger to the paralyzed side of the face.

Pulmonary Embolism from Mercurial Injections.—BLASCHKO (*Deutsche medicin. Wochenschr.*, 1892, No. 43, p. 965) reports in detail two cases and refers to several others in which the intra-muscular injection of mercuric salicylate in liquid paraffin in the treatment of syphilis was followed by pleuritic pain in the side, dyspnea, cough, blood-streaked expectoration, impairment of the pulmonary percussion-resonance, with the presence of moist râles on auscultation—symptoms that he ascribes to the entrance of minute quantities of paraffin, or of the insoluble mercurial salt into a vein and thence into a pulmonary vessel in which it becomes obstructed. In otherwise healthy persons the complication is attended with no serious results, but in tuberculous persons the consequences might prove injurious.

THERAPEUTIC NOTES.

Injections of Lactic Acid in the Treatment of Malignant Growths.—INGALS (*N. Y. Med. Journ.*, lvi, 24, p. 652) has reported the case of a man, fifty-nine years old, who for a year had been annoyed by the accumulation of an excessive amount of mucus in the throat and a sensation of unusual enlargement that interfered with deglutition, which for six months had been progressive. Eighteen pounds in flesh had been lost. The right tonsil was found increased in size to a diameter of an inch and a half, some thickening extending to the anterior pillar of the fauces and the uvula. The cervical lymphatic glands were not involved. A diagnosis of sarcoma was made and the tonsil was removed by means of the steel-wire écraseur; the thickened uvula was also removed. The wound healed in the course of three or four weeks, except in an area about a quarter of an inch in diameter. New deposits had, however, taken place at the site of the tonsil, giving rise to a tumor about half an inch in diameter and a quarter of an inch in thickness. Applications of a 60 per cent. solution of lactic acid were now begun, and a weak solution of carbolic acid was prescribed as a gargle. The appearance of the ulcerated area improved materially, but thickening was now noticed on the right side of the pharynx behind the posterior pillar, rapidly increasing in size until it attained a thickness of a third of an inch, a width of two-fifths of an inch, and a length of a little more than an inch. The man suffered from severe neuralgic pains, radiating from the tumor to the ear and side of the neck. As this mass could not be removed, it was injected with five minims of a 20 per cent. solution of lactic acid. Profuse bleeding followed each injection. The strength of the solution was gradually increased to 60 per cent., but it was found that from 8 to 10 minims of a 50 per cent. solution, injected in one or two places about three times a week, answered the best purpose. Nevertheless, the growth exceeded the reduction brought about by treatment, but its progress was manifestly modified favorably. The bleeding that at first accompanied the injections no longer occurred after a time. The injections were always made deeply into the tissues, and at times occasioned considerable pain. The general health and strength of the patient remained fairly good. On a few occasions a small quantity of cocaine has been added to the injections. The injection was followed by a spray containing morphine, gr. iv; carbolic acid and tannic acid, each gr. xxx; and glycerin and water, each f ʒiv.

For Hemorrhoids.—External hemorrhoids are first washed with an aseptic lotion, and an application of the following ointment is made three or four times a day:

℞.—Iodoformi	gr. v.
Ext. belladonnæ	gr. x.
Chrysarobin.	gr. xv.
Vaselin.	ʒj.—M.

Internal hemorrhoids are treated with suppositories, each containing:

℞.—Ext. belladonnæ	gr. ⅙.
Iodoformi	gr. ⅓.
Chrysarobin.	gr. j.
Ol. theobromæ	ʒss.
Glycerini	q. s.

KOSSOBUDSKI, *Wien. Med. Pr.*, 1892, No. 47.

Antipyrin-poisoning.—GUTTMANN (*Ther. Monatsh.*, Oct., 1892; *Brit. Med. Journ.*, No. 1665, Epitome, p. 87) has reported the case of a man who had taken one hundred and fifty grains of antipyrin in ten-grain doses twice a day. The first doses were followed by vertigo and impairment of vision. Then symptoms resembling those of the algid stage of cholera developed. The condition was one of collapse, with coldness of the extremities, hoarseness of voice and sunken eyes. The radial pulse could not be felt, and the temperature was 94.1°. The stools were solid; there was a deep rose-red rash upon the trunk. The man answered questions slowly, complaining of headache and noises in the ears. At times he could not see, but at others he would see two, three, or four inverted images.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. SPOROZOA AND THEIR RELATION TO CARCINOMA.

THERE is probably no line of recent foreign investigation the results of which will be awaited with greater interest by American physicians than those of the experiments now being carried out in the various parts of Europe on the minute organisms that have been found in the cells of nearly all carcinomatous growths, and the abundance of which appears at least to hold a direct relation to the malignancy of the growth.

The term Sporozoa[1] was introduced by RUDOLPH LEUCKART to distinguish certain low protistan organisms frequently found parasitic in man and other vertebrate animals from the Gregarines, which may readily be found crowding the viscera of arthropods and worms (*e. g.*, the proventriculus of grasshoppers and crickets), and which they resemble in producing hard-shelled germs (spores). The sporozoa (*coccidia*) have long been recognized in the intestinal tract and skin of man and the lower animals; they have been found in the muscles (*sarcosporidæ—sarcocystis hominis*)[2] and in the blood of man[3] and animals,[4] in molluscum contagiosum,[5] and in malignant papillary dermatitis (Paget's disease).[6]

As far back as 1847, R. VIRCHOW noticed certain enclosures within carcinoma-cells,[7] which he attributed to degenerative processes, and it was not until 1888 that the true character of these intra-cellular bodies was suggested.[8] During the four years that have elapsed since this announcement, specimens from over two hundred and fifty cases of carcinoma have been carefully examined, and the opinion of PFEIFFER and NEISSER fully confirmed.

Much discussion has arisen over the exact relation of the sporozoa to the diseased condition with which they are associated, but by far the most interesting and valuable recent contribution is that of W. PODWYSSOZKI and J. SAWTSCHENKO,[9] of Kiev, who preface their paper, entitled "Parasitism in Carcinoma, and a Description of the Sporozoa Parasitic in Carcinomatous Tumors," with an interesting and exhaustive review of previous work in the same field, accompanied by a bibliography of the subject. The first description of protozoa-like parasites in carcinoma-cells was made, as we have already remarked, by L. PFEIFFER, of Jena, in 1888, who found in the epithelial cells of a fresh, warm, melanotic carcinoma, certain organisms the developmental stages of which resembled very closely spore-formation, as seen in the microsporidia (*Plasmodiophora brassicæ*, or *Synchytrium mercurialis*). PFEIFFER'S observations were soon followed up by ALBARRAN[10] and THOMA.[11] Further investigation has since led PFEIFFER[12] not only to class these parasites with the sporozoa, but to the belief that the various forms of carcinomata will prove to be accompanied by different species of sporozoa.

PFEIFFER'S investigations were followed by NIL SJÖBRING,[13] of Lund, by VAN HEUKELOM,[14] of Leyden,

and AUG. KOSSINSKY, of Warsaw.[1] SJÖBRING found the parasitic sporozoa in eight cases, VAN HEUKELOM in nearly two hundred, and KOSSINSKY in ten cases. All of these investigators found the parasites most abundant in carcinoma of the breast, but at the same time demonstrated their presence in other forms. SJÖBRING agrees with PFEIFFER in classing the parasites among the microsporidia, and finds in them much resemblance to the parasites producing pebrine in silkworms, the discovery of which did so much to make Pasteur famous.

MICHAUD,[2] VINCENT,[3] and MALASSEZ[4] take sides with the aforementioned authors, while RAMSEY WRIGHT[5] and RUSSEL,[6] of England, oppose their views, and refer the bodies observed to the saccharomyces (Sprosspilze of the Germans), and the last writer claims to have found certain granules in the protoplasm of carcina cells, which, being fuchsinophile, he calls "fuchsin-bodies," and these he compares with the so-called "Altmann's granules," found not only in pathologic but in normal cells. KLEBS,[7] FIRKET,[8] BORRELL,[9] and SCHÜTZ,[10] all oppose the parasitic nature of the described cell-enclosures. Some consider them to be included leukocytes, or, perhaps, red blood-corpuscles; others, a product of a hyaline or horny metamorphosis of the cell-protoplasm. FABER DOMERGUE[11] sees in the so-called sporozoa inside the carcinomatous cells nothing more than was seen by VIRCHOW forty-five years ago, *i. e.*, degeneration-products of the epithelial cells themselves, while CORNIL[12] and HANSEMANN[13] see a possibility of mistaking various stages of karyokinetic cell-division for the sporozoa and their sporocysts. STROEBE[14] and STEINHAUS[15] admit the sporozoan nature of the bodies found in the cells, but oppose the idea that they have aught to do with the etiology of carcinoma. SUDAKEWITSCH,[16] as the result of the examination of sixty cases of different kinds, decides that "a carcinomatous growth of glandular epithelium in man, as well as in other animals, may follow the immigration of parasites belonging to the sporozoa." It will be seen that the subject had already received considerable attention when PODWYSSOZKI and SAWTSCHENKO began their investigations. After the study of the intra-cellular sporozoa in more than twenty cases of carcinomatous growths in various organs—testicle, skin, lip, breast, stomach—these writers assert "that the more evident the intensity of the carcinomatous growth, the more numerous the parasites in the cells; the spongier the growth and the greater the tendency to break down, the greater the number of sporozoa in the cells. The parasites were found most plentifully in medullary growths, and especially in primary and recurrent carcinoma of the breast. In cancroids of the lips and eyelids they were only sparsely present.

In order to study the parasitic sporozoa to the best advantage, pieces of the freshly excised carcinoma should be hardened in Flemming's fluid, the longer the better, then stained with safranin-anilin water, and washed in alcohol to which a few drops of picric acid have been added. The sporozoa are located either inside the cells or in the lymph-spaces between them. The parasites consist of spherical mother-cysts, containing falciform or semilunar embryos—characteristic of the sporozoa. Escaping from the mother-cyst, the embryos become disseminated, pass into the lymph-spaces, possibly into the capillaries, and into neighboring cells. That the bodies found in carcinomatous cells are sporozoa, and that they are parasitic, PODWYSSOZKI and SAWTSCHENKO hold to be demonstrated; they also favor PFEIFFER'S view that different parasites exist in connection with different varieties of carcinoma. The authors do not proffer any conclusion as to the relation of the parasites to the etiology of the disease—a question that remains to be investigated by the inoculation of animals with pure cultures of the parasites obtained from carcinoma, which has not yet been satisfactorily accomplished.[1] They, however, regard it as probable that the sporozoa exhibit here only an illustration of commensalism or symbiosis with epithelial cells. RIBBERT[2] opposes the parasitic nature of the en-

closures observed in the cells of carcinomata, holding that they are but degeneration-products of the epithelial cells or their nuclei. P. FOÀ, of Turin,[1] declines to accept many of SOUDAKEWITSCH'S figures as those of parasites, and he also holds that the so-called parasites of STROEBE and PODWYSSOZKI are found in non-carcinomatous tissues, and in those not of a new growth, and that they have to do with cell-development. FOÀ then describes and figures bodies that he finds in carcinoma of the breast and axillary glands, and that he considers without doubt to be parasites, but he also believes them to hold but a casual relation to the disease. To the criticisms of FOÀ, PODWYSSOZKI[2] replies that he has been incorrectly quoted, and that unwarranted inferences have been drawn from some of his statements, which seems to be the case.

We admire the conservative and cautious spirit evinced by the investigators of this important question thus far in declining to make any claim for the specific relation of the sporozoa to carcinoma; probably they, along with many others, have taken lesson from the battlefield of bacteriology, strewn with the lifeless remains of innumerable hasty hypotheses and specific germs.

There are one or two points that seem thus far to have escaped the attention of writers on this question. First, the allowance that must be made for certain tendencies toward growth or change recognized by students of variation and other questions of evolution, and which cannot be explained by environment. In the normal fulfilment of function certain organs begin at given periods of life to enlarge and become active, if for any reason, such as failure to marry, normal development is hindered, and we find the organ, urged on by this inherited tendency to change within a certain stage of life, taking on an abnormal growth. The statistics of carcinomata among women show that in about 70 per cent. of the cases the disease is located in the organs of generation—most frequently in the breast. In the majority of these cases, again, the patients are either unmarried or, if married, have never borne children, or so few as to fail to satisfy the normal tendency to activity in the organs concerned. Again, it must be borne in mind that carcinoma is one of the diseases that shows well-marked geographical distribution, being found more frequently among country people and in certain localities, than among inhabitants of cities and in other localities. These considerations enjoin investigators to great caution in throwing the responsibility of the disease on organisms of which so little is known as of the sporozoa.

THE NECESSITY OF THE RESTRICTION OF IMMIGRATION.

IF the press is to be taken as the exponent of popular sentiment, it would seem to be settled that immigration will be interdicted for the next twelve months. This sentiment is in a measure founded upon the expression of medical opinion, which is based on the belief that the greatest danger of importation of Asiatic cholera is through the immigrant-class and their baggage and personal effects. There are other reasons, practical and non-medical, why immigration should be restricted, and there are opposing arguments against restriction, but with these we have nothing to do in considering the subject from a medical and precautionary standpoint.

Judging from the history of epidemics of cholera in Europe, and the numerous scattered places on the Continent at which cholera still exists and has existed with a tendency even now to recrudescence, it is extremely probable that under favorable conditions later in the year, the disease will become more widespread and epidemic, and finally reach the United States. There seems to be a parallel between the conditions and the course of the disease in the years 1865 and 1866, and those of 1892 and 1893. Extraordinary measures will be required to protect the United States from the introduction of the disease during the coming spring and summer.

It is a fact substantiated by past experience that the greatest danger springs from the inflow of the immigrant-class and the fomites of disease concealed in their baggage and personal effects; and it stands to reason that if immigration were temporarily suspended, the problem of preventing a visitation of cholera would be greatly lessened, if not solved. It is a question whether the same end might not be accomplished without resort to so radical a measure. The English practice, which has yielded such favorable results, might be cited as a reason for hesitating before adopting so unusual and stringent a measure as exclusion; but the conditions in England and in the United States are quite dissimilar. In England, under the Local Govern-

ment Board, sanitary law and sanitary administration are made applicable to every part of the realm, and local sanitation is brought to a high degree of efficiency. Therefore, on account of this comprehensive system of local sanitation and the state of preparedness to meet and cope with disease, quarantine is limited to inspection and the isolation of the sick, with little interference with commerce and without the necessity of restricting immigration.

It is far different in this country. We are not yet prepared to throw down the barriers of quarantine, because our internal sanitary administration is only exceptionally adapted to meet the emergency, in the vast majority of places being neglected or only in its developmental stage. We are, however, making rapid strides in matters of sanitation, and may at no distant day catch up with England; but for the present, at least, it would be foolhardy to imitate England's practices without the facilities to carry out her sanitary methods.

If our quarantine defences were uniform, complete, and in the highest stage of efficiency, there would be less justification for a temporary suspension of immigration; but such, unfortunately, is not the case. Quarantine is in the transition-stage of administration. It is by no means certain what will be the issue of the discussion of the various proposed systems now before Congress; but this much is certain, that whether a National quarantine system shall be adopted or the local quarantines be continued and supplemented by Government aid and supervision, a considerable period will elapse before organization and equipment will be completed. This very uncertainty impedes the activity of preparation. Consequently, if the suspension of immigration as a temporary expedient will help materially to prevent our land from the threatened danger—and of this there can be little doubt—by all means let the Government resort to this expedient.

There is another consideration of great weight. This is the year of the Columbian Exposition, and it would be particularly disastrous if, by neglect to lessen the chances of the entrance of cholera, this disease should be introduced the coming spring or summer; but, laying aside this view of the question, if, with the great number of visitors attracted to our shores by the Exposition, immigration remains unrestricted, the immense passenger traffic would greatly enhance the risk of the importation of disease and seriously tax the ability of the quarantine authorities to meet the emergency, should cholera unfortunately break out.

For the protection of the public health and for the best advantage of the whole country, there seems to be no alternative but to suspend immigration as a temporary expedient made necessary by the existing conditions abroad.

SELECTION.

TAX ON QUACKS.

The recent suggestion of the Secretary of the Treasury that the tax on alcohol be increased fifty cents per gallon, in order to raise more money for the increasing expenses of the Government, seems to have met with a favorable response in some quarters, and the question of tariff and taxation will no doubt be considerably discussed by Congress in the near future.

In this connection, the wisdom of putting a heavy and permanent tax on all forms of nostrums and quackery will at once commend itself to all wise legislators who are working for the public good. A stamp-tax of this kind, say 25 per cent., on every form of secret or proprietary medicinal preparation of any kind, whether sold by the retailer, proprietor, manufacturer, or by advertising quack-specialists, would be no hardship to the public, as it would in nowise affect the retail price of these articles. All such manufacturers could easily afford to give the Government 25 per cent. of the retail price, and still have a very handsome profit left, as their net profit is rarely less than 500 per cent., and often very much more.

Legitimate preparations of the Pharmacopeia and other standard preparations, where the complete working formula is public property, should be exempt. But, as the success of quackery depends on secrecy and mystery, and as these two conditions enable unscrupulous persons to get a dollar for a few cents' worth of a simple remedy, it will be seen that there would be no injustice to anyone if a good fair tax were put on the business.

If the Government went still further, and required all nostrum and secret medicine manufacturers to pay a big license, and place on record open to public inspection a sworn statement of the exact composition, together with a complete working formula of each preparation, much good would result. And if, like insurance companies, they were also required to furnish heavy bonds, or make a special deposit, which could be forfeited under proper restrictions, provided their medicine did not do all that was claimed for it, the public would be still better protected, both in health and pocket, and no injustice would be done to the honest manufacturer of articles of real merit.

There is no good reason why the Government should not place the nostrum business on the same basis in its Internal Revenue Department as the manufacture of whiskey and tobacco. Analyses of these preparations should be made from time to time, and heavy penalties imposed if they vary from the sworn formula on record, or if any dangerous drug like morphine is being used.

England, which is said to be a free-trade country, taxes the nostrum business heavily, and derives a large and growing revenue from that source.—*New York Medical Times.*

REVIEWS.

AN ILLUSTRATED ENCYCLOPEDIC MEDICAL DICTIONARY. BEING A DICTIONARY OF THE TECHNICAL TERMS USED BY WRITERS ON MEDICINE AND THE COLLATERAL SCIENCES IN THE RUSSIAN, ENGLISH, FRENCH, AND GERMAN LANGUAGES. By FRANK P. FOSTER, M.D., Assisted by Eleven Collaborators. Volume III. Illustrated. New York: D. Appleton & Co., 1892.

THE third volume of this noble work, in which the medical profession of America takes a just National pride, extends from *Fascia* to *Minjak-lajam*. Praise of such a work is almost or quite superfluous, and criticism worthy of any attention may only be construed as proceeding from a hearty desire to make future volumes, if possible, more perfect. It is plainly impossible to avoid all errors and omissions, and one who has taken a hand even to a small degree in any undertaking similar to that of Dr. Foster and his co-laborers must be most disinclined to find fault.

The limits of our space will allow reference to but a few of the points that might be mentioned. Perhaps the most puzzling inconsistency that appears is the noteworthy lack of uniformity in weights and measures. Turn, for example, to the article *Iodum* or to *Hamamelis*. Several different systems are mixed in a sorry jumble that is certainly unscientific and is confusing to the average reader. It would have been better to choose one or even two systems and adhere to them throughout.

In giving the work its encyclopedic character there should have been scrupulous care that the scientific statements are accurate. For instance, by reference to the word *man*, it will be seen what we mean. From the words, *Man is anatomically, etc.*, every assertion is either absolutely untrue or open to serious question.

A number of remarkable omissions have struck our attention, especially these: *Fuchsinophile* and *fuchsinophilous, globin, lactoglobin* (alluded to under *Milk*), *microphotograph* and *microphotography, jack-knife-posture, genu-cubital, microsozin, Gafsa button, katabolin, metabolin, karyokinesis, lumbo-colotomy, lumbodynia, macrencephalic, macrencephalous, metopism, micrencephalous, metrocyte, microaudiphone, microbicide, mattoid, masochism, mesoplast, mesopic, macromelus, maconie* (mentioned under *makiah*), *maidismus, macrorrhinia, manigraph, maritonucleus, mestosis, microdentism, microgyria, microsthenic, microtomy, microtrichia, metabolize, metapeptone, metaplasis, metapsychosis, metencephalous, macrocephalic, macromania, lymphangiofibroma, lymphadenism, luctic, etc.*

The identity of *hollek* and *hollyhock* is not noted. *Garget* is not properly the name of *phytolacca decandra:* the plant is called garget-root because of the vulgar belief that it is a remedy for garget. Moreover, garget is defined as "mammitis in the cow"; popularly it is applied to a similar disease of swine. Originally garget was a swelling of the throat, a quinsy—a meaning overlooked by Foster.

The interesting etymology of *matzoon* is not given.

There are a great many commensal organisms besides *guest gall-flies* to which biologists apply the term *inquiline.*

Milford Springs is in New Hampshire, not in Massachusetts.

Marteno, the popularly perverted form of *martynia*, finds no entry, though in literary use for the past fifty years.

Glastonbury is given as a noun, but is it not a short way of saying *Glastonbury thorn?*

But of this lexicon it must not be forgotten that any number of such slips can detract but little from its positive merits, both many and great, and which cannot or need not be mentioned here.

READY REFERENCE HANDBOOK OF DISEASES OF THE SKIN. By GEORGE THOMAS JACKSON, M.D. With fifty illustrations. Pp. 553. Philadelphia: Lea Bros. & Co., 1892.

THE author is favorably known as a worker in the field of dermatology. The volume, as the title implies, is a reference handbook, compiled upon the A B C plan, the diseases being discussed in alphabetical order, without attempt at classification. This we regard as a mistake, for the plan fails to bring together diseases nearly related in their nature. A study of the relation of diseases is a field worthy of careful cultivation. The whole subject of etiology and pathology is thereby elucidated, and, as a practical result, therapeutics is made rational. In the volume before us the aim of the author has been to consider the diseases from the standpoint mainly of symptoms, diagnosis, and treatment, the etiology and pathology receiving only scant consideration.

The subject-matter is condensed, and brevity, both of matter and diction, are notable features. The numerous synonyms of diseases in all the languages figure alphabetically in bold type throughout the pages—too conspicuously we think, for they detract from the importance of the author's own views, and moreover tend to confuse the reader.

The book is intended for the student, and especially for the active practitioner who desires to obtain information with the least possible trouble of reading or time. But the amount of the information is limited in a book of this size, owing to the plan of attempting to cover so large a field. The subject-matter is reliable and may be accepted as embodying the principles of dermatology as practised to-day. The opinions of some of New York's representative dermatologists are frequently quoted. The author's own experience, however, has been large, and his personal observations make the book valuable.

There is on every page an effort to bring the subject up to date, especially as to the value and use of the new remedies. Recently described diseases, such as kraurosis vulvæ, angio-keratoma, erythrasma, pityriasis rubra pilaris, and dermatitis herpetiformis, all receive brief or full description, and give further evidence of the statement already made that the book is up to the times. Dermatology is regarded from a practical view—witness

the chapter, for example, upon "Some Dermatological Don'ts."

There is nothing dangerous in the teaching. The treatment recommended, on the contrary, is conservative, and may in all cases be safely followed. It consists of the remedies and formulæ in general use, together with a sprinkling of the newer drugs and combinations, which, however, the author refers to rather than indorses from his own experience. In some cases his views are decidedly positive. Formulæ abound throughout the pages, and a short formulary selected from favorite authors concludes the volume. Photographs and woodcuts occur here and there, which add to the value of the book.

Tuberculosis of Bones and Joints. By N. Senn, M.D., Ph.D., Professor of Practice of Surgery in Rush Medical College; Professor of Surgery in the Chicago Polyclinic, etc. Illustrated with 107 engravings (seven of them colored). Royal octavo, pp. 520. Philadelphia: The F. A. Davis Co., 1892.

Within the past few years current English and American medical literature has been enriched, in a department which was previously nearly barren, by more or less that is worth reading on the subject of surgical tuberculosis. English writers have, however, by no means kept pace with their Continental colleagues in the appreciation of the immense importance of the subject, or in their contributions to it. Still less have they attracted attention by any original studies, and to the German and French authors we have had to look for most of our information. Quite recently, however, English authors seem to have awakened from their lethargy and to be more active in their recognition of the various tuberculous lesions and more minute and accurate in their description of them.

The present work of Dr. Senn's is most helpful in this direction, and is consequently most welcome. It deals with the whole question of the genesis and pathology of tubercle, of the various fates with which it may meet, and the various sequels of primary tuberculous infection. After devoting seven chapters to the general consideration of the subject, he takes up bone-tuberculosis, to which six chapters are assigned, and then joint and synovial tuberculosis, to which he gives eleven chapters. Among these are included sections on non-operative treatment, including that by tuberculin, and that by intra-articular and parenchymatous injection of iodoform, and of the various other substances which have at various times been recommended. Nearly half of the volume is occupied by a discussion of the disease as manifested in particular bones and joints, and of the operative treatment which should be practised for its relief. This naturally comprehends the topic of joint-resections, those which are now generally practised being described at sufficient length.

Like all of Dr. Senn's work, this book is most carefully prepared, and serves as a complete epitome of the subject. We naturally expect to find frequent mention of the names of Volkmann, König, Kraske, Krause, Schüller, Lannelongue, and Ollier, but the valuable contributions and suggestions of others less well known are not in the least slighted. The observations and facts of all modern writers are orderly arranged, and masterly tempered or interspersed with the results of the author's ripe knowledge and experience.

We find very little to which we could take exception or which we could wish to amend. Our main criticism is one that must lose much of its force in view of the circumstances under which the book has been produced, namely, that while written by an American, and published at home, it is yet essentially foreign. Such a book could hardly be based on purely domestic studies and observations. The American and English professions have not yet advanced in this particular direction to a point permitting this. Obviously, then, we need just such a work by which all may familiarize themselves with the characteristic lesions and appearances, as well as with the surgical pathology of tuberculosis, and we are really largely in Dr. Senn's debt for the attractive and complete way in which he has performed the task that he has assigned himself. His advice is always sound, and should be closely followed, particularly, *e. g.*, that upon the performance of atypical resections, p. 306, *et seq.* The author may possibly be charged with a certain disregard of American mechanical aids which are certainly superior to the foreign. For example, we would be glad to see some illustrations of the Taylor hip and knee splints, which are superior to all others, and of the Verity suspension apparatus for dressing certain severe cases of resection of the hip, pelvis, and spine. But after all, these are minor omissions, since it is with the pathologic aspects of the general topic that the work is more concerned.

All in all, the work is most valuable, and deserves the most general sale and study.

Hygiene and Public Health. By Lewis C. Parkes, M.D., D.P.H. London University. Third edition, with illustrations. Pp. 523. Philadelphia: P. Blakiston, Son & Co., 1892.

In the preface to this edition the author calls attention to portions of this book that have been rewritten and brought up to date, especially the article on diphtheria, and the chapters upon etiology and bacteriology in general.

In reading these articles attention is attracted to many statements to which exception can readily be taken. In the chapter headed "The Contagia" there appears the following statement: "With the exception of scarlet fever, relapsing fever, leprosy, suppurative and septic diseases, which rest upon a surer basis, there is still wanting in the case of all these diseases" (reference just having been made to anthrax, tuberculosis, glanders, actinomycosis, diphtheria, croupous pneumonia, enteric fever, etc.) "the complete chain of experimental proof necessary to establish the causal relationship of the organisms which have been described as associated with them."

In the same chapter (p. 412), in referring to the etiology of malaria, mention is made of only the bacillus of Klebs, an organism that is of no more than historic importance, and has nothing whatever to do with the causation of malaria. Nowhere in the book do we find a reference to the work of Laveran, Marchiafava, Celli, Richard, Councilman, Osler, Golgi, and many others, who have practically demonstrated the true nature of

the etiologic factor concerned in the production of this malady.

On the same page we read that Eberth's bacillus of typhoid fever (*enteric fever*, as it appears in the text) is scarcely distinguishable from the common saprophyte, the bacterium termo; this statement is difficult of interpretation, for the reason that the term bacterium termo is now obsolete, and it is hard to say what it did indicate when in use.

The article on enteric fever (p. 445) begins thus: "Typhoid, or enteric fever, *excepting its possible origin from a cow-disease, etc.*" (italics are ours). Under the head Diphtheria we learn that "the etiology of this disease is still to a certain extent veiled in obscurity." On page 222 is quoted the work of Dr. Thompkins, in which it was possible for him to demonstrate in the air of a part of Leicester, England, in which diarrhea was prevalent, a larger proportion of bacteria than in the air of districts not so affected, "and that these same microbes, when cultivated, possessed the power of inducing diarrhea in the human subject." (No reference to the original communication is given.) As is usual in English books, sewer-gas is indicated as being the cause of many diseases, the existence of which cannot be otherwise accounted for. In this work we find it standing either in causal relation or predisposing to diarrhea, typhoid fever, diphtheria, erysipelas, puerperal fever, pyemia, septicemia, hospital gangrene, and Asiatic cholera. On page 219 we learn that long-continued inhalation of diluted sewer-air tends to produce a general loss of health, while two pages further on we are told that men engaged in the occupation of cleaning out sewers become acclimated, so to speak. On page 209 we find that the bacillus of tuberculosis acquires a higher degree of virulence when exposed to the foul air of an overcrowded apartment, than it originally possessed on leaving the lungs of a tuberculous patient.

Space will not permit of a complete analysis of this book. That which is good in it is not new, and much that appears as new cannot, with the best intentions, be accepted as good. After the amount of conscientious labor that has been expended in recent years upon the etiology of infectious diseases, and the conditions that govern their spread, it is certainly depressing to find such statements as those quoted above appearing in a work dated 1892.

HUMAN EMBRYOLOGY. By CHARLES SEDGEWICK MINOT, Professor of Histology and Human Embryology, Harvard Medical School, Boston. 815 pp. 463 illustrations. New York: William Wood & Co., 1892.

PROFESSIONAL students of biology have reason to be grateful to Prof. Minot for the massive collation of embryologic data contained in the eight hundred pages of his recent work.

There has been nothing hitherto giving so comprehensive a view of vertebrate embryology, nor any book better adapted to the needs of the lecturer who wishes to brush up his knowledge previous to presenting himself before his class.

The book is evidently based upon the notes and summaries accumulated by the author during the years of his preparation for the chair he now occupies, and furnishes striking evidence of his great erudition in the field of embryologic research. The training of the writer in foreign laboratories appears to have rendered him purblind to the advantages offered by his own native tongue and to any good in the embryologic work of American investigators, himself excepted. One detects a most unpleasant captiousness in many of the references to the embryologic contributions of such well-known American embryologists as Ryder, Brooks, Whitman, Clark, etc. The employment in the text of such terms as Urei, Merit, Aulage, Deckschicht, Tubenleiste, Vorderdarm, Globules tardif, and a hundred other foreign terms, in place of English equivalents, deserves as little commendation as does the author's preference for English, French, and German colloquial terms in place of properly constructed Greek and Latin derivatives. It is scarcely in accord with the rules of modern scientific nomenclature to coin names like the "zones of His," or to perpetuate such as the "Cochin-China canals." As a rule, the style of diction is good, although the lip tends to curl now and then at such conceits as "the problem was fruitful of fruitless speculation." The chapter on "The Theory of Sex," and that on "Heredity," are most interesting reading.

Taken as a whole, the book deserves commendation, and will form a most valuable addition to the library of the medical specialist and the professional naturalist. The busy practitioner and the student with an overcrowded curriculum will scarcely find time for the *pros* and *cons* of the multitude of embryologic hypotheses, and Mr. Minot would place the public under additional obligation if he would sift out, from the tremendous mass of information contained in his book, the established facts and most generally accepted theories of embryology, and present them without discussion, in the shape of a handy volume, as has been done, for example, by Prof. Flower for the Horse, by Taylor for Anthropology, and by Bennett for Cryptogamic Botany. There is a real need for such a book.

HYGIENIC MEASURES IN RELATION TO INFECTIOUS DISEASES: Comprising in condensed form Information as to the Cause and Mode of Spreading of Certain Diseases, the Preventive Measures that should be Resorted to, Isolation, Disinfection, etc. By GEORGE H. F. NUTTALL, M.D., Ph.D. (Göttingen), Associate in Hygiene and Bacteriology, Johns Hopkins University and Hospital; Member of the Association of American Physicians, etc. Pages xii, 112. New York and London: The Knickerbocker Press. G. P. Putnam's Sons, 1892.

THIS handy little volume could not have arrived at a more opportune time, when so much general interest is being shown in the means of preventing the spread of infectious and contagious diseases. The subject-matter is compiled from the latest conclusions of the best workers in this field, and will be of value to anyone who is practically interested in the subject.

The book contains, among other subjects: General considerations upon thermal and chemical disinfection, with remarks upon the special agents and practical directions for their employment; precautions to be observed by physicians and nurses in attendance upon the sick; also precautions to be taken by the other inmates of the

house; care of the sick-room; the disposal of infected clothing and bedding, etc., in hospitals and private dwellings; disinfection of excreta, water-closets, cesspools, etc.; the disinfection of a room in which an infectious disease has existed; information as to the causes and mode of spreading of certain infectious diseases, and the preventive measures that should be resorted to; and surgical disinfection. Throughout the book "brevity" has been the watchword—a consideration that makes the work especially convenient for reference.

CORRESPONDENCE.

LOW-POWER OBJECTIVES IN MICROSCOPIC DIAGNOSIS.

To the Editor of THE MEDICAL NEWS,

SIR: In this day of microscopic investigations in the diagnosis of diseases, we find almost every practitioner of medicine in possession of a more or less valuable microscope, and doing a certain amount of microscopic work in some line or other. It is to be feared that the majority of these would-be investigators are led to the purchase of a microscope more from the fact that it is a popular "fad" than from real motives of investigation, or as an instrument facilitating the diagnosis of many diseases; but be that as it may, the fact remains that very few physicians not specialists in microscopic work are able to make correct diagnoses of even simple growths and neoplasms. I have observed, even among men who paid considerable attention to microscopic manipulation, that very few are able to tell with any certainty the difference between even well-marked benign and malignant growths.

There are certainly some good reasons for this, one of which is undoubtedly the fact that most of these men have taken up microscopic study after leaving institutions in which competent instruction in some of the fundamental principles of microscopy is given; but from personal observation I believe that the real difficulty lies in the fact that the majority of persons do not use objectives of proper magnifying power. There seems to be a fear of using too low magnifying power, and consequently the opposite result follows, and we find altogether too high a power being used.

The majority of amateurs seem to feel that any magnifying power of less than 500 diameters is too low, while experience shows that a power of about 100 diameters is much better for the ordinary diagnosis of tumors. With a power of 500 diameters the field of vision is extremely limited, and one sees more of the individual cells than of the general arrangement of structures. In other words, he looks for special landmarks and avoids the "bird's-eye" view. This, I believe, is the true fault. A field of the microscope may justly be compared to a landscape, with the landmarks of clumps of trees, rocks, etc., represented by clumps of cells and various structures. No person, in attempting to recognize a new country, would look at individual trees or stones, but would rather take a general view of the whole from some hill-top, and then confirm the opinion thus formed by more minute examination of the woods and plains. Just so with the "microscopic landscape" of a new tumor. The low power (say, 100 diameters) is the bird's-eye view, and the grouping and arrangement of cells will give a better clew to diagnosis than individual cells can, no matter how well stained or how clearly defined by the lens.

It seems almost impossible to shake from the minds of the general mass of physicians the idea that each neoplasm should have its own particular characteristic cell, peculiar only to itself. I believe it is the remains of this old idea that leads to the use of high-power lenses in attempted diagnosis. When the amateur microscopist will shake off this idea and confine his attention more to general views with lower power objectives, I believe he will find it much easier to make correct diagnoses, at least of benign and malignant growths.

Very respectfully yours,

E. H. WILLIAMS.

IOWA CITY, IOWA.

TRAUMATIC SEPARATION OF THE LOWER EPIPHYSIS OF THE FEMUR.

To the Editor of THE MEDICAL NEWS,

SIR: In the *Montreal Medical Journal* for March last, there appeared a paper by Dr. John M. Elder, of Montreal, on "Traumatic Separation of the Lower Epiphysis of the Femur." In it he refers to an article on the same subject, published by me in November, 1890, in the *Annals of Gynecology and Pediatrics*. He speaks of it as having appeared "some time ago," thus giving the idea that it was an old affair; he also says that he is "indebted to it for many references." He goes on to state that he has "managed to disinter from medical journals" over seventy cases; and concludes the text of his paper in these words: "Subjoined is a list of references to the literature of the subject, so far as I have been able to investigate it."

He then presents an accurate copy, even to a slight typographical error, of a list appended by me to my paper. He probably failed to notice the fact that eighteen of the items contained in it were not "disinterred from journals," but derived from books. In adding my article to it, he omitted both name and date.

Now the preparation of that list had cost me many hours of labor; and upon discovering Dr. Elder's bold and disingenuous appropriation of it, I wrote to the editors of the *Journal*, calling their attention to the matter. I also sent them a copy of my paper. My letter was handed by them to Dr. Elder, who wrote to me enclosing a draft of a "correction," which he proposed to insert in the *Journal*, apologizing for a "careless omission" of my name. This I declined to accept, and I wrote to the editors that my complaint was not of a careless omission, but of a deliberate and dishonest claim by another to work done by myself. At their suggestion I then wrote out for publication a statement, as courteously worded as I knew how to make it, considering the unpleasant nature of the facts, and sent it to them on the 12th of July.

On the 21st of that month the manager of the printing-office wrote me, saying that one of the editors was very ill, and the other two were abroad; and proposing to hold my letter until the return of those gentlemen, which he thought would be in time for the next issue of the *Journal*. To this, of course, I agreed.

Nothing more was done until November 22d, when I

wrote again to the editors about the matter, but they have made no reply.

I am fully confident that they unwillingly became accessories to Dr. Elder's literary theft; but am surprised that they did not feel constrained to promptly express their disapproval of it upon its being brought to their notice. By abstaining from so doing, it seems to me that they tacitly connived at it, becoming, in legal phrase, accessories after the fact.

When frauds of this kind are committed, it is not merely the individual that suffers; an injury is done to the whole profession. This injury is intensified if the error is condoned or winked at. It is upon this ground, and not from any desire for personal redress, that the present statement is made.

I am, Sir, respectfully yours,

JOHN H. PACKARD, M.D.

1924 SPRUCE STREET, PHILADELPHIA,
December 28, 1892.

EARLY OPERATION FOR APPENDICITIS.

To the Editor of THE MEDICAL NEWS,

SIR: If the subject is not worn threadbare, I should like to report the following abstract of a case recently under my care. It emphasizes one of the deductions in your editorial of the 10th inst.: "Do not hesitate, if the symptoms are growing worse, to open and explore."

W. D. V., a previously healthy, well-developed young man, was taken suddenly to bed with agonizing pain, at first referred to the epigastric region. Deep pressure elicited severe pain limited to a space about two inches square, deeply situated just where McBurney has described the appendix to be. The patient always insisted that "there is a lump there, causing my trouble." No tumor could ever be made out, but deep pressure always located the one seat of pain. The anxious face, the readiness with which all else was dropped and the patient's whole attention was absorbed by his abdominal trouble, were to me conclusive evidence of something very serious.

The history of the appendicitis is similar to that so often recorded. The bowels were moved daily. Hot poultices for three days were followed by ice poultices. Considerable morphine was occasionally required.

On the fourth day, I desired to cut and explore. Good authorities urged that, because no tumor was felt, operation might advantageously be delayed. Chill and sweat presented on the eleventh day. Operation was then performed and an ounce of pus was evacuated from a sac formed by the agglutination of the head of the cecum, the appendix, and the abdominal wall. The gut was of black hue, and friable. The appendix had discharged through a small hole in its neck. The parts were thoroughly washed out with boiled distilled water. The appendix and all gangrenous tissue were removed, a drainage-tube was carried through the lumbar region in the back, the peritoneum was sewed up, and the wound closed.

Everything did well and the hopeless case promised to recover. On the fourth day, however, a chill occurred and symptoms of shock set in. Examination revealed a small stitch-abscess over the peritoneum, whose wound was perfectly healed. The drainage-tube, it was found, did not drain. It was thoroughly cleaned out and the stitch-abscess was also treated with antiseptic attention, but the patient passed from the state of shock into collapse and died in six hours.

It seemed to me that in this case, operation had better have been performed early, say on the fourth day, before the pus had come. Secondly, when the shock (probably due to the rupture of the rotten gut) appeared, it had been wiser to have opened the peritoneum and placed sterilized or medicated gauze in the old abscess-site, covering the intestines well and leaving the wound open. Thirdly, in such a case a drainage-tube does not drain, and hence is worse than useless.

Respectfully,

T. R. CHAMBERS.

EAST ORANGE, N. J.

OBSTACLES TO A NATIONAL QUARANTINE.

To the Editor of THE MEDICAL NEWS,

SIR: I have read with interest your leader in the issue of December 24th, on National Quarantine, and I would like the privilege of a word in reply. The advantages of a National quarantine have of late been fully and ably stated and seem to be generally conceded.

In regard to the objections you raise, you admit that, with the exception of the alleged Constitutional obstacle, "no one of them is very strong by itself, and each one can be overcome if taken singly." Therefore they can be disregarded. As for the Constitutional question, as you say, every one admits that Congress can establish and control quarantines against foreign countries; but, if I understand you aright, the trouble you anticipate is that the State might refuse to abandon its own quarantine system, and that the State and National quarantines might conflict. If you will pardon me for saying so, I believe this objection to be wholly imaginary, for two reasons.

First, because if an efficient National quarantine were to be established, the local quarantines would doubtless pass into "innocuous desuetude," or out of existence altogether, because they would have no function to perform. If, on the other hand, the National quarantine should at any time prove to be inefficient, it could do no harm to have it supplemented by the local organization. I fail to see how a local quarantine can make the authority of the United States "practically *nil*."

It certainly could not admit any person or thing which the United States authorities had excluded, and if it stopped those which the National quarantine had passed, it would appear to be only an additional precaution, or, at the worst, an unnecessary one. That the double quarantine would present such an obstacle to commerce as to materially impede it is a contingency not very likely to arise, as it is not probable that a State will take measures to destroy the commerce of its own ports. The New York Chamber of Commerce is probably as much interested in this question as any body of citizens, and it has emphatically declared itself for National quarantine.

Secondly, it is a well-known principle of Constitutional law that where authority is granted, all powers are by implication granted which are necessary to enforce that authority; hence, if Congress has the power to establish National quarantine, and local quarantine should

prove to be an obstacle in its way, Congress has implied power to annihilate, if necessary, the latter.

Respectfully yours, J. H. PLATT.

LAKEWOOD, NEW JERSEY.

DIABETES MELLITUS FOLLOWING AN INCISED WOUND OF THE HEAD.

To the Editor of THE MEDICAL NEWS,

SIR: The case herewith reported presents features of interest that seem to make it worthy of publication.

P. H., a male, eighteen years old, was, with a companion, cutting down a tree, when the axe glanced, causing an incised wound over the temporal bone, about one and a half inches long and one-half inch deep. The wound healed by granulation and nothing more was thought of the occurrence until about a month later, when the man, who had previously seemed perfectly healthy, commenced losing flesh and voiding a large quantity of limpid urine, amounting in twenty-four hours to one hundred ounces or more. When first called to see the patient, I at once noticed the increased urinary discharge, and on examination found an enormous quantity of sugar present. The patient sank rapidly and succumbed about four days after my first visit. From the previous good health of the patient and from the fact that the symptoms appeared so soon after the wound of the head, it seems possible that there may have been a causal connection between the wound and the diabetes, there being no hereditary predisposition to the disease. Respectfully,

J. B. LOCKRIDGE, M.D.

DRISCOL, POCAHONTAS CO., W. VA.

ANTISEPTIC MIDWIFERY.

To the Editor of THE MEDICAL NEWS,

SIR: THE MEDICAL NEWS for November 26th last contains an article by Dr. Garrigues on that always interesting subject, antiseptic midwifery. It is somewhat unfortunate that Dr. Garrigues should quote, in support of his position, the statistics of the New York Maternity Hospital. The showing is not very favorable: in eight years the deaths have been 1 to 106 confinements; those from sepsis, 1 to 453 confinements. It seems to me that the statistics of the Preston Retreat, of Philadelphia, afford more convincing evidence of the virtues of antiseptic midwifery. Here is a maternity that, by a kind of natural selection, draws from the poor classes of a large city its most difficult cases; and yet the showing is 1000 cases without a death. (A case admitted in a dying condition from eclampsia has very properly been omitted.)

Respectfully, FRANCIS L. HAYNES, M.D.

LOS ANGELES, CAL.

HYDRIATIC OR HYDRIATRIC.

To the Editor of THE MEDICAL NEWS,

SIR: Allow me to say that though Dr. Sihler is correct in the use of the word hydriatic as an adjective applied to treatment or procedure indicating treatment or procedure with water, this word cannot with propriety be applied to some nouns, such as school or institute. Here the adjective hydriatic is correct, because it is derived from *ὑδωρ*, water, *ἰατρική*, medical treatment, a school or an institute for the medical treatment with water.

Hydriatic is a shorter word for hydrotherapeutic, expressing exactly the same thing. It would, therefore, be tautology to say hydriatic treatment, while hydriatic treatment would be correct.

Respectfully, SIMON BARUCH, M.D.

51 WEST SEVENTIETH STREET, NEW YORK.

REPORT OF CASES OF MORAL IMBECILITY, OF THE OPIUM-HABIT, AND OF FEIGNING, IN WHICH FORGERY IS THE OFFENCE COMMITTED.[1]

BY J. T. ESKRIDGE, M.D.,
OF DENVER, COLORADO;
PROFESSOR OF MENTAL AND NERVOUS DISEASES IN THE UNIVERSITY OF COLORADO; NEUROLOGIST TO THE ARAPAHOE COUNTY, TO THE ST. LUKE'S, AND TO THE DEACONESS HOME HOSPITALS.

DURING the past year I have been called upon to testify in the criminal court in several instances in which the subjects arraigned, all for the same offence, forgery, presented the same excuse, insanity. I have arranged these cases into three classes: moral imbecility, morphinomania, and feigning. As most of the persons assigned to each class present many features of interest, both to the lawyer and physician, I shall give histories illustrative of each group.

CASE I. *Moral imbecility.*—R. B. T., twenty-two years old, a male, and by occupation a printer, has been arrested for numerous forgeries. I have been unable to learn anything definite of the patient's family history, but from a letter written by his mother, in which she claims an exceptionally good record for the family, I think that she is mentally below the average. The young man is a decided blond, of medium height; he is slender, pale, and presents a weak and anemic appearance. His head is of fair size, but it is irregular in outline, and is in aspect decidedly different from the average head. He seems bright and intelligent, is said to be quite expert at his trade, and is a voluble and rather plausible talker. Of his life before his fourteenth year I have been unable to learn anything, but at this age he began to learn his trade, soon became addicted to the excessive use of cigarettes, indulged in alcohol and venery, contracted the habit of gambling, and not long after his fourteenth year he commenced to forge checks for small amounts. This he did in Pueblo, and, on being arrested, his family redeemed the checks and he was not prosecuted. After being released, he again committed forgery, never drawing a check for a large amount, but simply making them large enough to supply money for his immediate drinking or gambling purposes. He went to Kansas City, worked for a short time, but soon resumed his habit of forging checks to secure small sums of money. He was accustomed to draw a check in his own favor, signing it in the name of some imaginary party, and before the check went to protest he would secure money on another forged check and pay the amount of the former forged paper. He seemed to regard his actions as legitimate, provided he succeeded in paying the checks before they went to protest, and appeared unable to realize anything criminal in his acts. He finally succeeded in drawing the money on so many checks that he was compelled to leave the city to escape arrest. He returned to his family in Pueblo, again forged several checks, and was arrested. His family again came to his rescue, but warned him that if he were again arrested for forgery they would not try to shield him from the law. He came to Denver in the latter part of the year 1891, and before he had been in the city twenty-four hours he forged three or four checks, all for small amounts. To illustrate his actions I will read from his attorney's letter to me.

"DENVER, COL., May 24, 1892.

"The facts pertaining to R. B. T., so far as I have any connection with his case, and so far as I possess any knowledge of him as an individual, are substantially as follows:

"Some time prior to December, 1891, he was arrested and charged with the passage of some three or four forged instruments of writing. He caused himself to be entered, in one of the trials, as his own attorney, and defended himself with very considerable vigor, but, of course, without any technical knowledge, and the result was a conviction. The conviction was set aside for manifest errors, and I was assigned to defend the prisoner.

"I undertook his defence, and endeavored to establish an alibi, but was not successful. He was again convicted, and sentenced for a period of eight years to hard labor in the penitentiary. I took out a writ of error to the Court of Appeals, and upon a presentation thereof, was granted a supersedeas, wherein the bond was fixed at $1000. This bond was given and T. was again at liberty. He went to the town of Ouray, Colorado, and remained there several months, until his other cases, which had not been disposed of, were set for trial, and practically beat his way on the railways from Ouray to Denver, a distance of several hundred miles. Upon his arrival here, I succeeded in having his various cases continued to await the action of the Court of Appeals in the supersedeas case pending in that tribunal. I then explained to him (and he fully understood the facts), that the Court of Appeals would not pass upon his case prior to September or October (about six months later), and that, in my opinion, the case would be reversed, and in all probability his cases would never be tried, provided he would behave himself in the meanwhile as a law-abiding citizen should. He promised me a faithful observance of my instructions to him, and immediately thereafter, without any provocation so far as I can see, and with money in his pocket, enough to support him, and with a good trade as printer, at which he is an expert, he proceeded to forge some seven or eight checks for a gross aggregate amount not to exceed sixty-five or seventy-five dollars.

"In his earlier forgeries in 1891, which were likewise in very small amounts, he used the name, S. M. Simpson, and signed them either with that name or with a

[1] Read before the Medico-Legal Society of Denver.

name of similar sound. In his more recent forgeries, taking place a month or two ago, he used the same character of handwriting and the same name, with, perhaps, one exception. There has never been an attempt in any of his forgeries to feign any handwriting, and I think, with one exception, the payee in all of them has been the same."

The young man, in the latter part of May, 1892, was brought to my office, where I spent about two hours in investigating his case.

I found that all his forgeries had been committed solely and simply as a matter of convenience, and that he did not think he had ever committed forgery in a criminal sense. He never drew a check for more than a few dollars, just enough to meet his present wants, and seemed to believe that if he succeeded in raising the money to pay the check before it went to protest he had done nothing more than play a smart trick to secure money for a pressing necessity. All his actions sustained this view of his case. He had on more than one occasion drawn a check for a few dollars, when he had at the same time money at his room. He said he did this because it was more convenient to draw a check than to stop his gambling and go to his room for money. If he were unmolested, the next morning he would pay the check before it went to protest. He acknowledged that forgery, as ordinarily practised, was a crime and should be punished. He appeared to think that he was being persecuted, and did not realize that he had done anything wrong in forging a man's name to secure money, when he meant to pay the check himself, and prevent anyone losing anything by his actions. He is supremely egotistical and intensely selfish, and cannot realize that his convenience should be interfered with, even though the whole community should suffer on account of his actions.

At his trial for insanity in the county court, I testified that I believed him to be a moral imbecile, whose selfishness and egotism caused him to disregard all law when he wished to gratify some passing desire. The jury returned a verdict of insanity, and he was remanded to the custody of the sheriff until room for him should be found in the State Asylum. He is still in the county jail here, and has been since his trial, as our State Asylum is overcrowded. At his trial he ignored his insanity and tried to justify his actions on the score of expediency.

During his stay in the county jail he has written several long and interesting letters. In a letter to his wife, written a few days after he was adjudged insane, he exultantly recounts his triumphs in Denver. He tells her that through the shrewdness of his attorney and his own masterly way of conducting himself, the judge, the jury, the county attorney, and even an expert on insanity, have been deceived, and he has been declared insane. He informs her that he is not very bad, and that, although only two days have elapsed since the trial, he is already able to recognize his attendants; and one week's detention in the asylum, to which he feels sure he will be transferred in a day or two, will suffice for his complete recovery. His conduct in the jail has been overbearing to an offensive degree. He speaks to his attendants as though they were his vassals, declares that he is being persecuted, and pompously asserts that he is going to have the whole matter investigated. He insists on his attorney visiting him several times each week, and relates to him in great detail his real or supposed wrongs. He yet languishes in jail, but still remains the same overbearing, unconquered, self-important individual. This young man indifferently drew checks on any convenient bank, and with none of which had he ever kept an account.

We will now study the nature of moral imbecility and compare T.'s case with others that are on record.

Bucknill and Tuke, in their work on *Psychological Medicine*, in a foot-note on page 49, state: "In fact, the term moral insanity is now universally restricted to that morbid condition which results in immoral acts without apparent intellectual disorder." Dr. Crichton Browne's description of moral insanity, written many years ago, is regarded as one of the best. He says:

"Moral insanity is of frequent occurrence in early life. The intellectual faculties of the person affected by it remain entire and unimpaired. He is perfectly capable of perceiving and knowing and judging. He cherishes no delusion. He cannot in the ordinary and legal acceptation of the term be pronounced insane, and yet he is to all intents and purposes of unsound mind, and as much requiring guidance, restraint, and treatment as the furious maniac. He suffers from entire perversion of the moral principle, from the want of every good and honest sentiment. He is actuated by impulse, or by the most selfish, depraved, and cruel motives; he presents, in short, a perfect picture of a desperado or ruffian. The existence of moral insanity, like the existence of everything else, has been called in question, and at the present day there are not lacking those who will recklessly commit the moral monomaniac to the scaffold or the penitentiary, little thinking that in so doing they punish disease and not crime. We are forced to acknowledge moral insanity as an actual disease by the most cursory glance at the previous history of some of those by whom it is manifested. Many of them from being refined and virtuous, and upright and prudent, have become coarse and licentious, and dishonest and reckless. We believe that many of our jails and penitentiaries are peopled by such." (*Ibid.*, p. 244.)

Dr. Prichard, one of the ablest and earliest of English physicians to devote much time to the study of the form of insanity under consideration, remarked: "It seems not improbable that many persons, wrong-headed and perverse through life, and singularly capricious and depraved, would afford in reality, if the matter could be ascertained, examples of moral insanity, native or congenital." (*Ibid.*, p. 245.)

Bastian wrote many years ago: "There are certain beings who are moral imbeciles." "It is remarkable," he states, "what an acute intellect may sometimes coexist with an entire absence of the moral sense." (Reynolds's *System of Medicine.*)

Cases of moral imbecility are often difficult to diagnosticate. Some may take the form of so-called

kleptomania, some of pyromania, some may be impulsively homicidal or suicidal, others may be simply vicious and perverse, taking delight in acts of cruelty or in annoying their associates; while, in all, there is to a greater or less extent a loss of self-control.

In a recent brochure entitled *Prichard and Symonds; with Chapters on Moral Insanity*, Tuke gives a letter from Dr. Prichard to his (Tuke's) father, in which he says: "I am desirous of knowing whether you have observed (at the York Retreat) any cases of moral insanity. By that term I distinguish the mental state of persons who betray no lesion of understanding, or want of the power of reasoning and conversing correctly upon any subject whatever, and whose disease consists in a perverted state of the feelings, temper, inclinations, habits, and conduct."

Dr. Tuke himself describes the condition as being "not loss of memory, not delusion or hallucination, not any deficiency of talent or genius, not any lack of mental acuteness, and certainly no incoherence of ideas or language, but a deficiency or impairment of moral feeling or self-control, such being either the development of a character natural to the individual, or a departure from it, which contrasts most strikingly with its former traits." (*Brain*, part lvii, p. 126.)

Tuke says that the diagnosis of moral insanity cannot be made by any rule, but that each case must be studied and decided in relation to the individual himself, his antecedents, education, surroundings, and social status, the nature of certain acts, and the mode in which they are performed, etc. (*Ibid.*, p. 131.)

We have, then, in moral imbecility a moral perversion, with loss of self-control.

The young man, the history of whose case has just been given, is nervous, subject to attacks of severe headache, with slight fever, coming on once or twice each year, and lasting one or two weeks at a time. Early in life he fell into habits fitting a criminal of mature years, and forged checks for small amounts, from time to time, apparently as a matter of convenience. The amounts of money he secured on checks were always small, and the forgery was done in a routine and systematic manner. When asked in court if he did not know that forgery was a crime and punishable, he promptly replied that he did, and made no effort to explain why he had committed forgery. He was asked if he had not committed forgery. He said that he supposed he had, or, at least, people seemed to think he had. On inquiring if he expected to commit forgery again, he replied that he did not, as he had no desire to be imprisoned. Then he was asked what he would do if he wished to purchase a parcel of goods, if all his money should happen to be at home, several blocks distant. His answer was that he would either go and get his money, or give a check for the amount, then get the money and pay the check at his convenience. When asked if he did not know that this would be forgery, he indignantly replied that it would not, as he would not be trying to cheat anybody. Convenience with him is supreme law, and self-gratification the great object of life. Egotism and a disregard of the rights of others characterize all his actions. All of his actions with which I have become familiar correspond with the statements that he made to me and before the jury.

The next case that I wish to report is one of moral imbecility, complicated by the opium-habit. Alcoholics and neurotics are found in the family tree.

CASE II.—Mrs. W., twenty-four years of age, of Nebraska, is a large fleshy woman; mentally rather dull, and her mind acts slowly. As a girl, up to her sixteenth year, when she was married, she manifested few symptoms different from other girls of her age, except that she seemed wayward, headstrong, and somewhat eccentric. At her first confinement she became insane (form not known), and remained in this condition for several months. Shortly after her recovery from this mental aberration she became hysterical, peevish, and fretful, and developed kleptomaniac tendencies. When she went to a store to order groceries she would fill her pockets with articles of slight value. Many of these were absolutely useless to her. At times she ordered goods in considerable quantities to be sent to the houses of different persons, saying that she had been requested to leave such orders. Finally her lying and thieving propensities caused her to be such a nuisance that merchants ceased to believe or trust her. After a while she began to have hysterical paroxysms, of several hours' duration, during which she would lie convulsed and semi-conscious. About this time, some four years ago, she began the use of morphine. She had hysterical hemi-anesthesia that lasted a year. Some three years ago she began to attend the meetings of the Salvation Army, and by some of the religious fanatics she was considered quite an acquisition to their ranks, as she made as much noise and professed as great a change of heart and character as the best of them. One night, in their experience meetings, she arose and said: "I wish to tell what the Lord has done for me. Last night I slept in the arms of a railroad man; to-night I shall sleep in the arms of Jesus." Some one in the gallery inquired in a loud voice, "Are you engaged for to-morrow night?" The meeting went on till a late hour as usual. When it ended, and the people were leaving the house, she was seen standing in the vestibule looking searchingly at the male portion of the congregation as they were leaving the building. Finally, when most of the people had left, she inquired of a man if he knew the man who inquired if she were engaged for "to-morrow night," stating she would like to see and make an engagement with him.

I mention this episode in the life of this moral imbecile to illustrate the utter worthlessness and hollowness of all professions of reformation made by such mentally defective creatures.

Whether she had resorted to forgery before she came to Denver about two years ago, I was unable to learn. Her husband is small, insignificant-looking, and a worthless-appearing man. It seems that he and a certain other man were cognizant of her forgeries and profited by them, if they did not suggest and direct them.

Within a few months after she came to this city she had succeeded in passing eighteen forged checks, all for small amounts. They were all in the same handwriting, which did not differ materially from her usual writing, with one, or possibly two exceptions, signed by the name of the same person, and were nearly all, if not all, drawn in favor of the same individual. About the only variation that was noticed about the checks was a change of address on nearly every one. It was her custom to go into a store and order a small bill of goods sent to her at a certain address, and then offer in payment a check drawn for about ten or fifteen dollars. As the purchase that she had made did not amount to more than two or three dollars, she obtained, as a rule, about ten dollars for each check.

When she was arrested and committed to the county jail she was under the influence of morphine, and probably of whiskey. She claimed to have been accustomed to take from ten to twenty grains of morphine daily. I saw her, after her imprisonment, with Dr. M. Baker, and we soon succeeded in reducing the quantity of morphine to two grains daily, and in about one month we stopped it entirely. She gained considerably in flesh after the drug had been discontinued.

When she was being tried for the forgeries, at the request of the district attorney and the attorney for the defence, the court appointed Dr. McLauthlin and myself to make an examination into her mental condition.

We found no physical evidence of any organic nervous lesion, and physically she appeared to be in an excellent condition, notwithstanding that she claimed to be unable to feel the contact of substances or the prick of a pin in certain areas. On repeated examinations of the sense of touch and pain over different portions of her limbs we found the areas to change in size and situation from time to time; so that we were forced to the conclusion that she was feigning anesthesia and analgesia. She appeared to have but little regard for the truth, but exhibited great caution and deliberation in her answers to our inquiries concerning the forgeries, lest she should contradict herself. She claimed to know nothing of all the checks, save one, and to remember nothing of obtaining money or goods on any but this one. This particular check she said was given her by a male friend. When asked why she had given a wrong address when she obtained money and goods on it, she said that she did not want the merchant to know where she was stopping. On having her write her name and then showing her the identity of the handwriting on the forged checks and on the paper on which she had just written her name, she became confused, but stuck to her former statement that the check had been written and given her by a friend. On questioning her in regard to her actions on the days on which the seventeen other checks had been drawn and passed, it was found that she had a fairly good memory for everything that occurred on those days, except what took place in relation to the checks.

Dr. McLauthlin and I agreed that she was feigning, knew all about the forged checks and the obtaining of money and goods on them; and we further agreed that she was a moral imbecile. Before we were called into the district court to testify, she was taken to the county court and adjudged insane, and remanded to the care of her father and mother in Omaha, where, I have no doubt, she is still pursuing the even tenor of her ways, and probably visiting revival meetings and professing great change of heart.

In the county court I simply testified that the unfortunate woman was morally rotten, that she was a criminal and moral imbecile by inheritance, nature, and practice, without self-control to restrain her from following her evil impulses, and that she was incurable and would live and die a criminal and a moral blot upon the community in which she chanced to reside.

On comparing with each other the histories of the two cases just related it will be perceived that they vary greatly in certain respects. In one, the young man, there are no kleptomaniac tendencies; he is bright, intelligent, egotistical, and oblivious of the rights and privileges of everybody else; he will not steal, he abhors a thief, although he has not hesitated to take mean advantages of his partners in the gambling business; he is a systematic petty forger, to such an extent that he may be said to have a *penchant*, or almost a mania, for forging, yet his actions have shown that these forgeries have been committed rather for convenience than for the purpose of defrauding anyone; he seems to take pride and delight in obtaining money on a worthless piece of paper, and tries to pay the check before it is protested. In this he can realize nothing wrong. When confronted with his crimes he denies nothing, but acknowledges all, gives a detailed account of every transaction, his intentions, and the causes that led up to the forgery.

In the other, the young woman, kleptomaniac tendencies have been manifest for a number of years; she is dull, somewhat stupid, suspicious and deceitful; she exhibits no egotism, and apparently cares nothing for the opinions of others; she is not a systematic forger, but seems to have been actuated by a different motive than that shown by the young man; she desires to defraud, and by falsehoods keeps her address a secret; it is only comparatively recently that she has resorted to this method of gaining money, and when confronted with proofs

of her guilt she lies, and persists in lying, although she knows that she is not believed. She even denies all remembrance of obtaining money on more than one check, and this she maintains was not forged by her, although her own handwriting condemns her.

What is the difference? The young man belongs to a more definite and better class of moral imbeciles than that to which the woman is assigned. He does wrong because he sees and recognizes no wrong in what he does. In the woman two causes seem to be in operation—one a partial moral obliquity, and the other a delight in doing wrong because it is wrong.

There is one mitigating circumstance connected with the woman's forgeries, and this should not be omitted in summing up the character of her actions. It was observed that when she obtained money on forged checks she was always joined by her husband or by another man soon after she left the store. This would suggest that these men were acquainted with her doings while in the store, and probably had suggested the forged checks as a means of obtaining money. Now take a person morally depraved as this poor unfortunate creature is, and he becomes the dupe of every designing individual who happens to have influence over him.

CASE III.—The third case that I report is quite brief. It is in relation to the criminal action of a morphine-habitué, a young man, whose family and personal history I was unable to obtain, further than that he had been accustomed to the free indulgence of morphine for eight or ten years, and during the last two or three years preceding the crime had been in the habit of taking from twenty to thirty grains of morphine daily. He was accompanied by two young men to a second-hand clothing store, obtained a suit of clothes for which he was to pay six dollars, produced a check drawn in his favor for twelve dollars, signed it, and received six dollars in change. Nothing wrong was observed with the young man during the transaction. Shortly after this the check was found to be worthless, and the man was arrested. He denies having any knowledge of obtaining either clothes or money on the check, although it was proved that he had obtained both, and had written the check himself. The plea of amnesic insanity was set up by the defence, on the ground that he had taken about ten grains of morphine just before the transaction.

I was appointed by the court, at the request of the defence, to testify in regard to the man's insanity at the time of the transaction, and in regard to the influence of morphine on the mind. I found that the man remembered almost everything that occurred on the day of the alleged transaction except the transaction itself.

After giving the attorney for the defence my opinion in the case, and telling him that I should have to testify in the main against his client, I was requested by him to take the witness-stand. He asked me only one question: the influence upon the mind of the free and prolonged use of morphine. I testified, of course, that it made a moral wreck of a man and lessened and destroyed his self-control. On cross-examination I was asked (although the defence objected to the question) the immediate influence on the mind of the usual quantity taken by morphine-habitués before the period of stupor was reached. I answered that it brightened and quickened the intellect, improved the memory for the time being, and put the opium-user in the best possible mental and physical condition. I was asked if the habitué of morphine knew right from wrong under such circumstances. I answered that he would distinguish quite clearly, although he might be unable to resist doing wrong. The young man was convicted and sentenced to the penitentiary.

I believe that this man was a tool in the hands of his two evil companions. They probably planned the crime and he carried it out. He probably realized that he was doing wrong at the time of the act, but moral control was gone, and the hope of obtaining money for further indulgence in morphine made him a ready victim for almost any crime suggested to him.

CASE IV.—The fourth and last case that I report requires a little more careful study than Case III.

The patient is a young man of twenty-two years of age, newly married, and of an intelligent, mild, and prepossessing appearance. He is a college-graduate, and has received a fairly good business education. He came to Denver about one year before his arrest in this city, and like the majority of people who do not belong to one of the three professions, he entered into the real-estate business. His life before coming here, so far as I was able to learn, had been exemplary. He met and married a young and rather prepossessing lady whom he had led to believe that he was doing a prosperous business and had become possessed of considerable wealth. He said that he was agent for a tract of land in Texas, for which he claimed that he would make twenty-five thousand dollars. He bought three houses and lots, for which he had no money to pay. He purchased expensive furniture for his office, and for this he gave a check on the bank in which he had formerly kept an account. His grocery bill amounted to seventy-five dollars. He drew a check payable to his wife on the same bank for more than the amount of the grocery bill, went with her to the groceryman, and had her pay his bill with the check. Within a few days he drew several checks for various small sums for debts contracted and purchases recently made. Suddenly he disappeared and was not found for several days. During this time the checks had been protested. He was found staying in the unoccupied houses which he had recently bought. He was arrested and committed to jail, and I was requested by the attorney for the defence to make an examination of his mental condition.

After inquiring into his life, habits, and mental

powers up to the time when he began to draw checks for which he had no money in bank to pay, I took up in detail, beginning with the first, each amount for which he had drawn worthless checks, and found that he remembered with remarkable accuracy the minutest circumstances connected with each transaction. He could give the amounts of each check, the date it was drawn, and for what the debt was contracted. When I asked him why he drew the checks when he had no money in the bank, his invariable reply was that he knew he had some nine hundred dollars in bank, and if the bank said he had not, it made a mistake. I asked him if his bank-book did not show that he had no money on deposit in the bank. He said it might, but that he knew the bank was mistaken, as he had deposited about nine hundred dollars in the bank since his book had been balanced. I continued my inquiries into the time (several days) during which his whereabouts had not been known to his wife or his friends. For this period he claimed to have no memory whatever.

On inquiry at the bank, I learned that he had not made the deposits which he claimed to have made, and that he withdrew his account from the bank some nine months before the fraudulent checks were drawn. I found that he remembered his arrest while staying in the unoccupied house, but he said he could not tell how long he had regained consciousness before his arrest.

Without going into the reasons for my opinion, I told the young man's attorney that I felt positive that his client was feigning. I heard nothing of the case until about three months after my examination, when I was summoned by the district attorney to appear in the criminal court to testify in a case of alleged insanity. On my arrival in court I found the case was that of this young man. The district attorney did not know that I already had knowledge of the case. During the progress of the trial I learned from witnesses who testified in the case that several of the statements which the prisoner had formerly made to me and his attorney were false. After adjournment of court I began an examination of the prisoner in the presence of his attorney, the office of the district attorney not being represented. I found the young man exceedingly nervous and despondent. Several developments in his case had occurred during the time that I had been in court which proved that he had not been truthful either with me or his attorney. I abruptly demanded of him to know why he had dealt falsely with his attorney and me, and told him that I feared it was too late to do anything for him, but advised him to tell us the whole truth and we would do all that we could for him. He expressed regret that he had not been truthful, and with tears in his eyes frankly acknowledged that he knew when he drew the checks that he had no money in bank, but excused his conduct on the ground that money was due and promised him, and he had expected to collect this and deposit it in bank before the checks were presented. Failing in this, rather than tell his wife and creditors his unfortunate condition, he had tried to secrete himself, when he was arrested.

It is needless to say what the verdict of the jury was.

We may inquire, What should be done with the criminal moral imbecile, or with the criminal moral reprobate caused by the use of alcohol or opium? Shall he be allowed to go free on the plea of insanity and irresponsibility? The community has certain rights as well as the individual, and those of the former are greater than those of the latter. It seems to me that the only feasible solution of the subject is to make all criminals who are not suffering from those forms of insanity that necessitate their confinement in an asylum responsible to the law for their conduct, but to modify the punishment according to the degree of self-control possessed by each class. Neither the insane asylum nor the penitentiary is a fit place for the moral imbecile, or for the criminal insane in general. It is an outrage to subject the insane to the constant presence and association of the criminal insane, and it is equally unjust and inhumane to confine the latter with the hardened criminal, such as are found in our jails and penitentiaries. Every State should have a separate place provided for its criminal insane.

Owing to the indefatigable and intelligent efforts of Dr. Peterson and his co-laborers in the cause, the State of New York is about to establish a home for its epileptic population. Let us hope that this good work may spread to every State in the Union, and that not only the epileptic but also the insane criminal, of which the epileptic population forms no insignificant proportion, may be equally well and suitably provided for.

THE ETIOLOGY OF GASTRIC ULCER.[1]

BY CHARLES G. STOCKTON, M.D.,
PROFESSOR OF THE PRACTICE OF MEDICINE IN THE UNIVERSITY OF BUFFALO, N. Y.

THE mucous membrane and the deeper structures of the stomach may suffer loss of substance from a variety of processes that may with truth be called ulceration. Thus, ulceration may take place from traumatism, corrosives, scalding fluids; from tuberculosis, syphilis, scurvy, or from serious blood-changes; from extensive burns, from continued pressure, and from other causes that disturb the nutrition of the part.

However, for an ulcer occurring most often in young women, which is usually round; having about it healthy mucous membrane; its margin being abrupt and clean-cut, so that in old cases it has a distinct punched-out appearance (as Rokitansky aptly describes it); generally found alone, but occasionally having one or two companions;

[1] Read at the meeting of the New York State Medical Association, in New York City, November 17, 1892.

located, as a rule, on the posterior wall near the pylorus, and often near the lesser curvature; almost invariably associated with an excessive secretion of hydrochloric acid, and not infrequently with anemia—which is called the "simple," the "solitary," the "round," the "perforating," the "peptic," the "ulcer of Cruveilhier"—for this there has been suggested no cause that is satisfactory, or that answers all important requirements.

It is not to be supposed that one can draw an uninterrupted and perfectly distinct line of separation between true round ulcer and all other forms of gastric ulceration. It is probable that in many instances the processes are so intermingled and confused that even the fullest knowledge of the facts would leave differentiation incomplete; but the fact must, nevertheless, not be lost sight of that in the classical "round ulcer" no theory of etiology so far suggested has proved to be altogether satisfactory. Before discussing this part of the subject, however, let us consider what we know of the causes of gastric ulcer in general.

It is widely believed that the bacilli of tuberculosis passing through the stomach may invade the intestinal mucous membrane, and yet that this organism, while not destroyed by the gastric secretion, has not been shown to be a cause of local trouble in the stomach. Notwithstanding this, there are now reported numerous authenticated instances of tuberculous disease of the stomach,[1] and occasionally extensive ulceration of the mucosa is seen.

Syphilis, according to histologic examinations made by Guozot,[2] has been shown to be a cause of ulcer, and Heller[3] thinks that syphilis plays an important rôle in congenital ulcer, of which a number of cases have been reported.

The disintegration of neoplastic tissue can scarcely be considered as ulceration of the stomach, although it is well known that carcinoma often finds its seat in the place of a preceding ulcer. Albertoni,[4] however, reports a case in which an ulcer was complicated with adenoma of the stomach, and believes that the ulcer resulted from a previous growth of this nature. Turner[5] describes a circumscribed superficial slough of the gastric mucous membrane in a man suffering from pyemia following a fracture of the tibia, and similar cases resulting from septic emboli have at long intervals been reported.

I have seen erosions of the gastric mucosa resulting from extravasations of blood into its substance, in cases of purpura and scurvy; and, according to Wales,[6] such lesions and even distinct ulceration are rarely absent in the latter affection.

Quioroza[7] reports cases of gastric ulcer resulting from dysentery, puerperal septicemia, and typhoid fever, and this author believes that the affection is the direct result of numerous diseases of the body.

An interesting and ingenious explanation of the affection is that given by Wiktorowsky,[8] who maintains that from chronic catarrh the establishment of the chronic interstitial process, up to perforating ulcer of the stomach, is but a continuous chain; but proof of this theory is wanting. Nevertheless, Peter[9] and others hold that round ulcer is the result of a preceding gastritis, and the increased local temperature is mentioned as evidence in that direction. It will be remembered that Cruveilhier[32] held to the inflammatory origin of the disease. There has been a general acceptance of the views expressed long since by Virchow, that the ulceration follows hemorrhagic erosions resulting from disturbances of the circulation; that "the interruptions of the circulation are for the most part due to morbid conditions of the gastric vessels, and particularly to a hemorrhagic necrosis of the mucous membrane." This hypothesis at once opens a wide avenue for causative factors, and if it were not for certain reasons, hereafter to be mentioned, the attempt to point out a special process in the development of the ulcer described by Cruveilhier would be profitless.

It is most natural and sensible to suppose that, given a hemorrhagic necrosis of the mucosa and the presence of the active gastric juice, the part would become digested, and the typical excavation, so well described by Rokitansky, would appear. This position is substantiated by clinical observations, post-mortem discoveries, and laboratory experiments, so that one cannot deny that ulcers are thus established.

In 294 cases, Berthold[10] found disease of the circulatory apparatus in 170; while Steiner reports such changes in 71 cases out of a total of 110, finding particularly endocarditis, endaortitis, and endarteritis. Thrombosis in various parts was demonstrated 48 times. Litten[11] saw a perforating ulcer with a thrombus in the splenic artery, and Janeway[12] describes a like case in which the ulcer was directly due to a fibrinous plug found in the gastro-epiploic artery. Provost and Cotard produced ulcerative changes in various parts of the alimentary canal by introducing tobacco seeds into the aorta, and other similar experiments are on record; and, as might have been expected, Letulle[13] claims to have established the infectious origin of the gastric ulcer.

By experimental means, hemorrhagic necrosis, and, later, ulceration, have by several investigators been produced in dogs. Ritter[14] succeeded by poking a dog's stomach with a cane, and Decker reports like results after feeding to dogs hot gruel. Quincke relates experiments on dogs with gastric

fistulæ, in which the mucosa was injured by pinching, excision, or by tying off small portions; by thermal irritation; by caustics.

The animals showed no subsequent distress, nor was the digestion impaired, but the ulcers disappeared after from four to twelve days, although the repair was delayed materially by rendering the dogs anemic by bleeding. Von Sohlern[15] thinks that a vegetable diet, by increasing the proportion of potassium salts in the blood, acts against the formation of ulcer, and he mentions the infrequency of the disease among vegetarian people. Silberman[16] repeated these experiments with modifications, and reached the conclusion that ulcer might be caused by arterial anemia, venous hyperemia, portal stasis, circumscribed hemorrhages, or reduced alkalinity, and suggested that the hyperacidity of the gastric juice might depend upon the lowered alkalinity of the blood. Ulcers following blows upon the abdomen in dogs[17] and men[18] are reported, and it is well known that the condition is often seen after severe external burns.[19]

Localized pressure as a cause is mentioned by Rasmussen,[20] and M. Pettit[21] has recently described a fatal case which apparently arose from pressure and rubbing exercised by a bony protuberance on the inside of the lower end of the sternum. Zielinski,[22] of Warsaw, in a recent paper, considers as a cause of gastric ulcer the narrowing of the lumen of the vessels of the stomach from traction made by enteroptosis. Duodenal ulcer not infrequently follows external scalds and burns,[23] and occasionally also the stomach is the seat of like lesions;[19] and severe injuries of various kinds, experimentally made upon animals,[24] have been followed by hemorrhagic necrosis in various parts of the body and in the stomach by ulcers.

Precisely how these changes are brought about is not clear, and it is therefore not surprising that, as Niemeyer has suggested, the nervous system may be a possible factor in the process. Indeed, it was with this in mind that Ebstein made the experiments just alluded to, which were a part of a series of investigations undertaken to show the relation that exists between certain severe injuries and gastric ulcer. Repeating the well-known experiments of Schiff, Ebstein reached somewhat different conclusions; but in the main, both of these investigators agree that injury to certain parts of the central nervous system (optic thalamus, pedunculus cerebri) is competent to establish ulcus ventriculi. Similar results followed a half section of the spinal marrow, and any great and often-repeated irritation of the sensory nerves led to quite uniform changes in the gastric mucosa. Talma[25] was able to produce ulcer by exciting spasm of the muscular coat of the stomach, through prolonged stimulation of the left vagus. He suggests that the so-commonly-present hyperacidity may thus affect the pneumogastric. Apparently this throws light upon the mystery of the relation between external burns and ulcer, and is at any rate highly suggestive of a possible nervous cause operating in cases seen clinically.

Whatever the exciting cause, the lowered alkalinity of the blood on the one hand and the excessive acidity of the gastric juice on the other are generally acknowledged to be active contributing causes. Pavy[26] teaches that the normal alkalinity of the blood successfully opposes ulcer, by preventing the autodigestion of the stomach. This self-preservation on the part of that organ has been shown not to be dependent upon this condition, however, since Samuelson made the blood neutral, and yet the stomach continued to resist its own secretions. This fact throws discredit upon the theory so long and securely taught by Cohnheim,[27] and we must now conclude that in such investigations as these of Silberman's[40] the resulting ulcers were from some other change in the blood besides the mere lowering of its alkalinity. The views of Ewald,[41] that the blood-changes, to be operative, must be such as lower the resistance of the living cell, are more acceptable. There is apparently a close relation existing between the lowered alkalinity and the hyperacidity. The intimacy of the relation pointed out by Pavy has been acknowledged by many. Grime[42] quotes fifty-three cases of ulcer, all of which had hyperacidity, and concludes that it is due to the preceding chlorosis, and that, with those two conditions present, the slightest injury to the mucous membrane may form the focus of an ulcer.

Riegel[43] and his students insist that the great excess of hydrochloric acid is the invariable accompaniment of gastric ulcer; and while this accords with my own experience, and undoubtedly is true of classical ulcer, there are undoubtedly cases, as shown by Ewald,[44] that are not only without hyperacidity, but even show hypoacidity. The importance of the acidity in delaying the healing, is, as Riegel states,[45] very great, and that it has a marked influence in establishing the lesion is most probable, but the fact remains that ulcer may exist and persist without hydrochloric acid, just as it may appear in those who have not antecedent anemia.

In view of the foregoing facts, necessarily stated incompletely and with brevity, it seems justifiable to suppose that while ulcerative processes dependent upon tuberculosis, syphilis, pyemia, scurvy, and other serious dyscrasias, may proceed in the gastric mucosa, and while simple anemia with lowered alkalinity of the blood assists the process, while hyperacidity of the gastric contents greatly favors the change, there must still be some other as yet un-

known cause which in a certain group of cases leads to the necrosis, besides the accidental changes from thrombi and emboli, such as have already been cited above.

The reasons for this claim are: First, that the affection shows itself particularly in adolescence or before middle age, when there is the least probability of vascular changes; second, that it appears most frequently in women, who are less often subjects of arterial diseases than men; and third, because, with remarkable frequency, the ulcer selects for its site the lesser curvature and posterior wall of the stomach near the pylorus, a portion of the economy that is not often invaded by emboli, and a region of the stomach especially rich in anastomosing vessels. In a large number of cases Buchmüller[46] found over 93 per cent. on the posterior wall near the lesser curvature, and no certain cases under fifteen years. In the Berlin statistics not one case was found under the tenth year, and the greatest number between the twentieth and thirtieth years. It is occasionally congenital,[50] and one altogether exceptional case was found in a man, said to be one hundred and twenty years old.[51] Greiss[47] found from three to five times as many scars in women as in men, and over 90 per cent. appeared on the posterior wall near the lesser curvature; and although many of these appeared in middle, and a few in advanced life, the beginning of the trouble was doubtless in earlier life, as Leube[48] has pointed out. Statistics abound in similar statements, as may be learned by consulting Welch's splendid monograph in Pepper's *System of Medicine*.

From the foregoing facts, namely, the propensity shown by the affection to select a certain site in females, and to appear in early life, has naturally arisen the suggestion that this form of ulcer may take its origin in some unknown but definite neuropathic change—trophic, vasomotor, or both of these. It has seemed to me remarkable that this view has not gained more adherents, since by no other evident hypothesis can these points in its natural history be explained.

In reflection on the matter, it has occurred to me that somewhat analogous processes are to be witnessed in other parts of the body, and that by using these as illustrations some insight into the pathology of round ulcer may be gained. For instance, the well-known proclivity of herpetic eruptions to attack particular points under especial conditions is brought forward, and attention is called to this common disease, that, depending upon nerve abnormality, is found, not only upon the skin, but upon the mucous membrane of various parts, including the mouth and throat, with a view of asking whether it might not select for its appearance the pyloric extremity of the stomach, and so lead to ulcer.

Again, there is something most suggestive in that extraordinary disease known as idiopathic hematoma auris, which is seen not infrequently in the insane, which invariably appears in the concha, rapidly reaches maturity, and disappears only after destruction of tissue and marked cicatricial deformity. It is interesting to note that the affection has been seen occasionally in those having no mental disease, or other known disability.[49] In a recent paper on this subject, Dr. H. G. Matzinger refers to the complex nerve-supply of the ear, with especial reference to the sympathetics, and concludes that othematoma is a neuropathic affection, seen generally, but not invariably, in those suffering from central nerve disease, in which the sympathetic system is seriously involved. Why might not some similar process have for its local expression the posterior wall, or lesser curvature of the stomach near the pylorus, than which no part of the economy has a more complicated and involved innervation?

One is led also to think of the striking manifestations in that curious affection, Raynaud's disease, with its predilection for the fingers and toes, with its advancing steps of syncope, asphyxia, and necrosis of the parts.

It is not impossible that asphyxia of certain spots of the gastric mucosa may occur from analogous causes, whatever they may be, and the tissue thus put to a disadvantage would be well calculated to suffer erosion from the active gastric juice.

If Morvan's disease is not found to be a phase of syringomyelia, it also might be advanced as an instance of local necrosis, something like that which may appear in the stomach.

A few years ago I saw at the clinic of my colleague, Professor Roswell Park, a case of intense interest, that of a neurotic girl, who had a series of painful and persistent ulcers along the forearm and the leg, following the tracts of certain nerves. The parts bordering the ulcers were uninvolved, and in every way healthy; the ulcers themselves followed the appearance of limited gangrenous spots; they were deep, with abrupt walls, and were exquisitely sensitive. They had for years resisted the treatment by very able men, but those on the arm were permanently cured by a thorough stretching of the external cutaneous nerve, practised by Park. There was something about the appearance of these ulcers that reminded one of the typical round ulcer of Cruveilhier, and it does not seem to me absurd to suppose for the latter a somewhat similar origin.

In concluding this view of the subject, it appears natural to assume that the stomach, like other parts, may suffer loss of substance from a variety of causes; but as regards simple round ulcer, it must have a more precise and definite etiology.

Unquestionably, the impoverished condition of

the blood, leading to lowered resistance of "the living cells," and the persistent presence of hyperchlorhydria, must of necessity put the tissues to severe strain—but there is wanted yet another factor. The object of this paper is to suggest that, by the influence of some process analogous to herpes, or to idiopathic hematoma auris, or to Raynaud's disease, or to herpetic gangrene—some distinct and persevering nerve-perturbation — we may best explain the recognized but unaccounted-for feature of the clinical history as to location, age, and sex.

PNEUMOTOMY TWICE IN THE SAME PATIENT FOR THE RELIEF OF TUBERCULOUS ABSCESS AND GANGRENE OF THE LUNG; RECOVERY.[1]

BY JOHN BLAKE WHITE, M.D.,
PHYSICIAN TO CITY HOSPITAL, ETC., NEW YORK.

UP to a period not quite twenty years ago the annals of surgery had been silent respecting operative procedures on the lungs. Dr. Rickman J. Godlee, a well-known authority on this subject, regards surgical treatment of pulmonary cavities as still in its infancy, but believes that in a certain class of cases the measure will advance in efficiency as it will assuredly in frequency. It is quite true, nevertheless, that the great Father of Medicine two thousand years ago referred to abscesses located within and without the lung-structure, and even defined the point of selection for operating and draining them; but we owe to Estlander the credit of first originating and establishing, in our day, surgical treatment for defined diseases of the lungs.

In this class of cases prompt and correct diagnosis is a condition essential to cure. As soon as the character of the case is determined, operative procedure should be instituted without delay—as, while it is quite true that ordinary abscess of the lung may terminate in recovery, no case of gangrene of the lung has been known to recover without surgical interference.

Before describing a remarkable case of recovery from gangrene of the lung, through surgical resort, in my own experience, I deem it appropriate to briefly allude to a few selected experiences related by other surgeons in the same direction; and I purposely exclude all empyemas, confining my remarks exclusively to strictly pulmonary abscesses.

Morton, of Philadelphia, in his work on *Consumption*, in 1837, has related a very interesting case of tuberculous abscess of the lung, communicating by a fistulous canal with an abscess on the back, resulting in death, which, if treated with our present knowledge and boldness in managing such cases, would in all probabilty have terminated in recovery.

The patient was admitted to the hospital February 1, 1833. During the previous year he had had a slight cough, and severe pain between the shoulders, especially on the right side, accompanied by hemoptysis. The pain continued, and after a time a swelling appeared on the right side of the

[1] Read at the meeting of the New York State Medical Association, held in New York, November 15, 16, 17, 1892.

chest posteriorly between the base of the scapula and the spine, and this continued to increase in size.

After two months the symptoms became aggravated, active hectic set in, and the expectoration was profuse and purulent, with occasional hemoptysis. Anorexia, emaciation, and great debility supervened. The tumor was elastic, evidently containing air, and was tympanitic on percussion. Treatment by internal medication for six weeks resulted in no improvement, till the apex of the tumor ruptured spontaneously, discharging a large amount of fetid pus of the same character as that expectorated. The opening was then enlarged and a pint of pus escaped; the patient obtained great relief, but the case being left to Nature entirely for so long a time, the benefit was but temporary; the patient in four days became delirious and died, no doubt from septicemia. At the autopsy a fistulous opening was found extending directly from the pulmonary cavity to the dorsal abscess.

Dr. Samuels[1] has related the history of a patient at the London Chest Hospital, who came complaining of cough, pain, and dypsnea. On examination he found absence of chest movement of the left side, with anterior and posterior dulness, tubular respiration, and increased vocal fremitus. The temperature rose in a few days to 103.8° and soon fell again. Night-sweats and free fetid expectoration very soon set in. Upon inserting an aspirating needle between the fifth and sixth ribs two ounces of fetid pus were withdrawn. At the point of puncture tumefaction followed, so that a free incision was subsequently made, liberating about three ounces of pus. The cavity was washed out and drained. Subsequently a portion of the seventh rib was resected and a cavity the size of an orange was discovered in the lung. The patient suddenly died on the fourteenth day in an attack similar to an epileptiform seizure, followed by paralysis of the right arm.

Dr. A. V. Meigs[2] has reported the case of a boy, eight years old, who had been ill for three years, commencing with an acute attack in which an abscess of the lung developed. Examination of the right lung revealed dulness in the region of the third rib, with a cracked-pot sound, extending down to the liver. The respiratory sounds were harsh; expiration was prolonged at the base of the lung posteriorly, where the respiration was feeble and harsh, with dulness over this area also. Large quantities of pus were expectorated after violent paroxysms of coughing. Dr. Meigs believed from the symptoms and the distinctly clubbed fingers that there was a cavity in the chest containing pus. An incision was made, free drainage established, and the patient recovered.

The following case of gangrene of the lung cured by a surgical operation has been reported by Drs. Paul and Perier:[3]

A man, aged fifty-eight years, was attacked in June, 1891, by a severe bronchitis, soon resulting in fetid expectoration. The presence of a focus of disease was revealed on auscultation, situated over the middle of the left lung, and characterized by a large zone of very fine râles. Antiseptic inhalations were resorted to, without preventing the progress of the disease, which evinced all the symptoms of gangrene. By December, symptoms of septicemia became alarming. Cavernous sounds were most intense over the second intercostal space. Dr. Perier made an incision through the intercostal space and pleura, seized the lung with a pair of fine forceps and kept it in contact with the parietal pleura. An incision was then made into the lung, which showed healthy tissue; a Lister forceps was thrust into it in the direction of the abscess and withdrawn with the blades expanded so as to leave a free exit to the pus. On introducing the finger a round opening was felt. This cavity was dressed, after cleansing with a cotton tampon soaked in a solution of one per cent. of chloral, and afterward touched with camphorated naphthol. Two drainage-tubes were inserted side by side and the wound closed. Air circulated through these tubes freely at each inspiration and expiration. The fits of coughing ceased at once, the odor disappeared from the sputa, and fever subsided. Improvement progressed steadily. Two weeks after the operation the drainage-tubes were replaced by a piece of salol-gauze, and at the end of seven weeks the wound had healed and the patient was completely restored to health.

Dr. Runeberg,[1] of Sweden, has described a case of successful pneumotomy for pulmonary abscess following pneumonia, and he has collected the reports of eleven cases similar in character. Discarding three of the eleven cases on account of uncertainty of diagnosis, five of the remaining eight recovered, three resulted fatally, though not as a result of the operation. He believes pneumotomy indicated when the diagnosis is clear and the abscess is accessible; but he deprecates the use of antiseptic irrigations, and thinks thorough drainage sufficient. Among other authorities may be mentioned Dr. Arthur Neve,[2] who has reported a case of abscess affecting the upper and anterior part of the right lung successfully operated upon. Drs. Bearman and Pengrueber[3] have reported a case operated upon for the relief of an abscess located in the middle portion of the right lung. Thiriar[4] has operated upon a case successfully for the relief of an empyema communicating with an abscess-cavity in the right lung. Dr. Pasteur[5] records a very interesting case of gangrene of the lung in a boy seven years old, which was subjected to operation. The amount of repair which took place under unfavorable circumstances was most encouraging, though the case proved

fatal. He expresses the opinion that an operation performed earlier might have saved the patient's life.

A very interesting case of pleuro-pneumonia, followed by gangrene of the lung and abscess, upon which he operated with success has been reported by Okell.[1]

The following case of abscess of the lung, reported by Dr. Francis Huber,[2] terminating in recovery after operation, is also of interest:

A boy, four years of age, had been ill for nearly a month. When first seen, October, 1888, he had fever, irregular chills, and distressing cough. Physical examination proved negative, except as to the presence of an area of flatness, with distinct bronchial breathing, in the right infra-clavicular and mammary regions. Pus was obtained by an exploratory puncture. When an incision was made, pleural adhesions were found, and pus was discovered in the substance of the lung. The cavity, having been drained, subsequently contracted, a small fistula remaining for about ten months. Some difficulty was experienced in locating the cavity after the thorax was opened. No bad results followed irrigations of the cavity; forcible injections, however, occasioned paroxysmal coughing, which ceased when the injected fluid was expectorated—indicating its admission into a bronchial tube.

The 8th of April, 1890, Miss A., aged thirteen years, having a tuberculous family history, was attacked with croupous pneumonia, involving especially the right lung. During this illness she was under the care of Dr. T. A. Pease, of Norwood, N. Y. At a critical juncture she was seen in consultation by Dr. J. Reynolds, of Potsdam. The case ran a favorable course, and, as Dr. Pease reported, reached a crisis on the morning of the ninth day after the attack, when resolution set in, and the patient rapidly recovered. The temperature, circulation, and respiration became normal within three weeks. After recovery there remained no cough and no expectoration, except that resulting from chronic catarrh of the air-passages, to which she had been subject since she was three years of age.

At the end of the second week of convalescence the pyrexia returned, the temperature rising to 102° F.; the respiration became more labored, the cough spasmodic, the expectoration difficult and scanty, and the pain and tenderness about the side affected more pronounced. Dulness upon percussion now extended from the angle of the scapula upward until it involved the entire lower half of the lung, both anteriorly and posteriorly.

The case was now believed to be one of interstitial pneumonia, with fibroid degeneration and infiltration. This condition, with temporary improvement and relapses, and with marked disturbance of the digestive functions, continued until the case passed out of the hands of Dr. Pease.

The care of the patient next devolved upon Dr. Reynolds, of Potsdam, who continued attendance until January 1, 1890, when the patient was taken to the Adirondacks for several weeks, whence she was brought to New York. Soon after her arrival in New York I was summoned to see her, and upon examination I found her suffering from an acute broncho-pleuro-pneumonia, engrafted upon an old unresolved pneumonia, which had degenerated into a fibrosis of the right lower lobe, involving part of the middle lobe. She was under my care about two weeks. After she had recovered sufficiently from the attack, she was carried to Thomasville, Georgia, where, under the care of Dr. Cortelyon, she remained until the end of the following spring, when she returned to Norwood. Soon after her return home she was again placed under the care of Dr. Pease, from whom I received the following account of her condition:

"Miss A. coughs less than before her trip South, and her respiration is improved, though marked dulness is present over the central portion of the right lung, with loud, moist râles heard on auscultation. Last evening she was brought into my office retching, vomiting, coughing, and expectorating an intolerably fetid, greenish matter. She continued to expectorate a large amount of this offensive sputa, and was frequently harassed by violent paroxysms of coughing, accompanied by violent irritation of the fauces, with frequent emesis."

All internal remedies, judiciously and skilfully employed by Dr. Pease, having proved unavailing, and the case intensifying in gravity, a consultation was determined upon, and I was called to Norwood. On my arrival, July 26th, 1890, I proceeded to examine the patient, and Dr. Pease and I came to the conclusion that a large area of the right lung had become gangrenous, that an abscess had resulted, communicating with a bronchus. An exploratory puncture was made, which resulted in fortifying the conclusion we had arrived at. The patient presented a pinched and extremely cachetic appearance—indeed, her condition seemed in every respect so critical that we thought no time should be lost, and decided to operate at an early hour on the following day.

Assisted by Drs. Pease and Larkin, the patient being put under the influence of chloroform, I proceeded to make an incision in the sixth intercostal space, about one inch anteriorly to the axillary line. The different layers of tissue, including the pleura, were in turn divided, and a careful examination of the seat of lesion was made. The finger was pushed through the intercostal space, and came in contact with the smooth outer surface of the condensed lung. A fluctuating point was discovered, into which the knife was directed. This liberated about two ounces of very fetid pus, having the same odor as that which had been expectorated. The wound was next irrigated with an antiseptic solution, a drainage-tube was inserted, and antiseptic dressings were applied.

The patient slowly rallied, with the aid of hypodermatics of brandy and digitalis. There was

[1] London Lancet, 1888.

[2] Archives of Pediatrics; THE MEDICAL NEWS, October 17, 1891.

immediate relief of all distressing symptoms, and after a few days of depression she began to improve, and continued to gain strength until the discharge ceased.

The cavity continued to drain until, at the expiration of two months, the discharge was so much reduced that it was judged expedient to remove the tube. A month after the removal of the tube urgent symptoms set in. Distressing paroxysmal cough, fever, and greenish fetid expectoration, so offensive in character that it often excited nausea and vomiting, again imperilled the patient's life.

Dr. Pease discovered an area of dulness on the posterior aspect of the lower lobe of the right lung, and again summoned me to visit the patient, which I did on the 22d of September, 1890. Upon examination, I found quite a favorable condition about the seat of the previous operation, but discovered a region of decided dulness in the posterior part of the lower lobe, extending under the angle of the scapula upward. An operation similar to the first appeared necessary. With the assistance of Dr. J. Reynolds, of Potsdam, and Drs. Pease and Larkin, of Norwood, I reopened the thorax an inch posteriorly to the axillary line, meeting with the same condition of the lung as at the first operation. On opening the cavity, several ounces of very fetid pus escaped, with fragments of necrotic tissue, and a piece of gangrenous lung-tissue, having the appearance of the remains of a well-defined ruptured bronchus. A good-sized soft-rubber tube was inserted, and after thoroughly washing the wound with an antiseptic lotion, appropriate dressings were applied. For three weeks the pus, which drained freely, was very fetid, but the patient was immediately relieved of cough, expectoration, and septicemic symptoms.

Air circulated freely through the drainage-tube, upon both inspiration and expiration, and often during the process of irrigating the cavity the antiseptic solution would be coughed up.

The drainage was kept up for a period of eight months before the tube was removed. The patient is now restored to a condition of health superior to that enjoyed in early childhood—two years having elapsed since the last surgical procedure. Dr. Pease wrote me that menstruation, which had been arrested during her illness, became reëstablished the November following the last operation, and was accompanied by a marked disturbance of the whole system. The clubbed finger-nails which had so disfigured her hands had disappeared. She is able to take a full amount of exercise, and her present physical condition is one of perfect health. In this case regular irrigations of a mild solution of hydrogen dioxide were practised with much benefit.

There is every reason for the exercise of great care and caution in the irrigation of pulmonary cavities. The danger of the frequent and indiscriminate irrigations of pus-cavities in the lungs is strikingly shown in the case reported by W. Pasteur,[1] of London, in which the patient was signally relieved by the operation, but sank rapidly on the tenth day.

[1] British Medical Journal, October 20, 1888.

Bowditch, of Boston, condemns too diligent washing out of pus-cavities, pulmonary and pleural, an opinion which meets with my support; and he further ventures the statement that the proportion of cases in which irrigation might be required is possibly one in four hundred. I am, however, of the opinion that in gangrenous cavities, such as the one under consideration, irrigation is safer than in cavities emitting more laudable pus. I have in consultation seen an instance of metastasis to the shoulder joint promptly follow irrigation of a pleural pus-sac, which occasioned a most serious involvement of the joint, requiring an operation for its relief. The patient, however, ultimately made a good recovery, without any impairment of the use of the joint.

In the performance of all operations on the lungs the strictest and most diligent observance of antisepsis should be unfailingly carried out.

Cases of gangrene of the lung are never too far advanced for surgical interference, even though presenting evidences of profound septic contamination.

Spillman and Haushalter consider it necessary to excite adhesion of the pleura before operating, but I do not consider this an essential procedure; and though it may be a more favorable condition under which to operate, delay for pleural adhesion to occur might prove, in some instances, decidedly unsafe. Resection of a rib is seldom required in the very young, except to facilitate the discovery of abscess in doubtful cases.

A corrugated white-rubber tube, to the value of which my attention was called by Dr. E. H. Grandin, better meets the requirements in these cases than the ordinary soft-rubber drainage-tubes commonly made use of. The former do not so readily yield to the pressure of granulation-tissue, and, therefore, maintain drainage more satisfactorily and for a longer time.

1013 MADISON AVENUE.

MITRAL STENOSIS IN PREGNANCY; WITH CASES.[1]

BY Z. J. LUSK, M.D.,
OF WARSAW, N. Y.

THE question as to matrimony with women having unmistakable organic disease of the heart can admit of but one answer, and that emphatically in the negative. Rarely is a physician's consent or advice sought by the contracting parties, for the very good reason, in the first place, that nearly always the disease is unsuspected, there being no signs denoting a perverted state of the health; and secondly, if there were such signs, the young Juliet would prefer

[1] Read at the meeting of the New York State Medical Association, held in New York, November 15, 16, 17, 1892.

taking the chances of married life, rather than the opprobrium of ultimately evolving into that state which bears the euphonious title of "old maid."

Under the subject of Cardiopathia and Pregnancy, Dr. Parvin[1] quotes Jaccoud as asking the question, "Has the patient suffered from a cardiac lesion?" "If she has never suffered, he sees no reason to forbid marriage," but adds, "Her social condition must be considered." "If she has to work during pregnancy there is much to be feared, but if she can be properly cared for, follow medical advice, and pass the last half of her pregnancy in almost absolute rest, she may marry." Jaccoud further relates a case in his private practice, in which a "young lady had for eighteen months ardently desired to marry, and that, had a negative answer been given, mortal syncope might have followed." The fallacy of such an argument is too apparent. The chances of mortal syncope following a refusal to permit marriage would be more favorable than those of syncope attending the cardiopathies in the pregnant state. The augmented duties of the married woman, the painful consequences following pregnancy and maternity, and the alarming infant-mortality—all of these should be sufficient to dissuade the most sanguine, and to clear all doubts about entering upon the married state. It would be a great error to assume that a woman could safely marry if not at the time suffering from the valvular disease, nor would her environment permit of favorable consideration.

If stenosis of the mitral valve is present, serious trouble will certainly develop as soon as the heart is called upon to perform the increased work incident to the last months of pregnancy. The demands upon the maternal system begin about the sixth month; subsequently to this time great changes continually occur. The enormous development of the gravid uterus, with its intricate vascular apparatus, as well as the growing fetus, calls for an increased amount of blood, the normal constituents of which are undergoing change, the solids diminishing while the liquids increase in quantity. While there is an augmented supply of blood,[2] "the frequency of the pulsation of the heart remains unchanged. For this alternate contingency dilatation of the cavities becomes a necessity, and for the same reason, arterial tension is increased." It is plainly evident that the hitherto weakened heart must begin to show evidence of overwork.

Mitral stenosis is essentially a disease of women and children, and the diathesis to which a majority of cases owe their origin is the rheumatic. It may in some instances owe its etiology to chorea from neurotrophic disturbances. Loomis[3] asserts that such cases are confined to children, and recover after a few years. Duroziez[1] discourages the theory that mitral stenosis, pure and simple, is of rheumatic origin, and records eight cases occurring in children, but adds that they were subject to rheumatic attacks later in life.

The object of this paper is not so much to discuss the etiology of mitral stenosis, as to consider the management of such cases when they occur to us in actual practice. They are almost always emergency-cases, desperate in character, and demand the best energy and the most prudent management of the physician. Fortunately they are of rare occurrence. In the last eighteen years I have had upward of twelve hundred cases of labor, and among this number only two of mitral stenosis. There have been the usual number of those who gravely assert that they have heart-disease and cannot take anesthetics. There are also cases in which physicians have accepted the statements of patients, without making careful physical exploration, and thus often nourish the belief that there is organic trouble, when careful examination fails to discover the physical signs, and their long-cherished ideas are exploded. Sir Andrew Clark describes six hundred and eighty-four cases of valvular disease occurring in his private practice in the year 1887, and says that "in a large majority of these cases the disease was unsuspected."

The symptoms of mitral stenosis are few. The most characteristic phenomenon is described by Loomis[2] as a loud churning, grinding, or blubbering presystolic murmur. It is of longer duration than any other cardiac murmur, on account of the time required for the blood to pass through the narrowed and obstructed orifice. It ends with the commencement of the first sound. The apex-beat is synchronous with the purring thrill. The murmur is heard with maxium intensity a little above the apex-beat.

CASE I.—On May 5, 1890, I was called to see Mrs. K., a primipara, aged thirty-one, well developed, and weighing about 135 pounds. The environment was all that could be wished. I was informed by her husband that she was seven and a half months advanced in pregnancy, and that she had been unusually well until about a month before, when she began to have gastric disturbance, more or less nausea, with the bowels constipated, and not readily responding to laxatives. I learned that her brother (who was a graduate of the University Medical College of New York, but not at the time engaged in the practice of medicine) had occasionally seen and advised her. Indeed, up to this time no other medical aid had been sought. I found the patient sitting up, pale, and complaining of intense nausea, almost con-

[1] Annual of the Universal Medical Sciences, 1888, vol. i, p. 192.

[3] Pepper's System of Medicine, vol. iii, p. 666.

[1] Annual of the Universal Medical Sciences, 1888, vol. i, p. 192.
[2] Pepper's System of Medicine, vol. iii, p. 668.

stantly retching, and occasionally vomiting whitish mucus tinged with bile. The stomach rejected everything taken, even to water. The pulse was rapid and weak, the respiration hurried, the tongue moist and covered with fur, the breath offensive, and the bowels had not moved for several days. She also complained of sleeplessness. I advised an enema of warm water and soap, a sinapism applied over the epigastrium, cracked ice p. r. n., and also prescribed small doses of fluid extract of ipecacuanha, gtt. xv to half a glass of water, and of this gave a teaspoonful every fifteen minutes. This has often relieved the distressing nausea of pregnancy when other remedies have failed. To the question whether she had any heart-disease she gave a negative answer, and said that if her bowels could only be relieved she would be all right. I also left a powder of sulfonal to give her sleep.

On the following day her husband informed me that the enema had been followed by negative results; that the nausea was better; she had rested better and was more cheerful. I was requested to consult with her brother, Dr. Gouinlock, whose idea of the case was that she had worn very tight-fitting corsets and that she was now paying the penalty, the gravid uterus encroaching on compressed organs, and he knew of nothing to relieve her condition. I advised pil. cathartic. co. to move the bowels, and potassium bitartrate, a teaspoonful in a glass of water, and of this a dessertspoonful once in two hours. I did not see Mrs. K. at this time, nor again until Friday evening the 8th, when I was hastily summoned. I found the patient in bed, very much exhausted, the countenance pale and pinched, the pulse 130, rapid and weak, the respiration 38, and constantly retching. Dyspnea was marked. There was no edema of the extremities. Dr. Gouinlock was present. I advised a hypodermatic injection of morphine and atropine, gr. $\frac{1}{4}$ and $\frac{1}{150}$. Dr. Gouinlock informed me that the family was very susceptible to the effects of morphine, and objected to giving more than one-tenth grain. I considered that her condition of extreme prostration required more heroic treatment, and advised the repetition of the dose until complete quiet was secured. No examination of the heart was made at this time; the patient was very restless and tossing about in bed. The urine showed no traces of albumin. Dr. Gouinlock was left in charge of the patient during the night. I was hastily called again about 1 A M., and was told that Mrs. K. had had a sinking spell. On arrival, I found her unconscious, the face and extremities bathed in cold perspiration, and in extreme collapse. There was no pulse at the wrist, and the respiration was slow and intermittent. I learned that she had continued restless up to a few moments before, when suddenly the head drew back, the body became rigid, and she had a regular tonic spasm. She was pale and colorless; the heart was now beating and pounding tumultuously; nothing but a churning sound could be heard.

At this juncture Dr. M. D. Mann, of Buffalo, N. Y., was summoned by special train, and arrived in about two hours. In the meantime I began the administration of chloroform, the color gradually returning to the face, the heart becoming steadier, the pulse appearing at the wrist, and when spoken to the patient moved the eyes and apparently became conscious. On examination of the heart there was a loud presystolic murmur, with an occasional clacking sound. On palpation a distinct purring thrill was communicated to the hand. Digitalis and brandy were given hypodermatically. Under this treatment her condition continued to improve and things began to look more hopeful, when suddenly the eyes were drawn upward, the head backward, and tonic spasms of the whole body followed, lasting about two minutes. Respiration became apparently suspended. The beating of the heart became loud and tumultuous, cold perspiration again appeared upon the face and extremities, and she had every appearance of rapidly sinking. The muscles, however, soon began to relax, and under chloroform-inhalation the heart became less tumultuous, and color again returned to the face. I repeated the former treatment. At this time I made examination *per vaginam*, and found the os dilated, easily admitting the middle and index fingers. Chloroform was administered and I began dilating the cervix, which yielded readily. In the meantime Dr. Mann arrived, verified my diagnosis, and continued the treatment. About 4 A.M. another spasm ensued, lasting about one minute. The patient rallied slowly from this. Dr. Mann continued the dilatation, and when sufficient to permit, he applied Tarnier forceps and she was soon delivered of a stillborn male child. The patient did not rally, but gradually sank and expired about 5 A. M.

CASE II.—Mrs. H., primipara, a well-developed Englishwoman, twenty-nine years of age, had one miscarriage two years before at three and a half months. Her husband was in poor circumstances and she was obliged to work. She was seven months advanced in pregnancy, and had been doing well until two weeks before, when she had an attack of fainting, as she termed it, and following this she had nausea and vomiting, which continued up to the time I was called. She had also been troubled with a hacking cough. Her tongue was moist and covered with brown fur, the breath was very offensive; the bowels constipated; the pulse 140, the rhythm being regular. Dyspnea existed, and she also complained of sharp pain in the precordia. On palpation there was a distinct purring thrill communicated to the hand and diffused over the apex. There was no increased area of dulness. Near the apex a loud, prolonged presystolic murmur could be heard. The apex-beat was synchronous with the purring thrill. Dr. Loomis[1] holds that the diagnosis of mitral stenosis depends upon the existence of two physical signs, viz., "the purring thrill and a loud, long blubbering presystolic murmur."

Examination *per vaginam* found the os slightly dilated, easily admitting the index finger. The patient was put to bed, an enema prescribed to move bowels, and morphine, gr. $\frac{1}{8}$, atropine, gr. $\frac{1}{150}$, were given hypodermatically, with fluid extract of ipecac, gtt. xv, in half a glass of water, a teaspoonful every

[1] Pepper's System of Medicine, vol. iii, page 667.

half-hour as required. Brandy and digitalis were also ordered. I called again on the morning of the 12th and found her condition better; the bowels had moved, and nausea was not as obstinate. I continued the remedies, adding aromatic spirit of ammonia. On the morning of the 13th there was less dyspnea; the pulse was 120; vomiting was less frequent; the temperature was 99°; and the heart's action was less tumultuous. She continued to improve until the 25th, when I discontinued daily calls. I had advised the family fully of her condition and the necessity of keeping her quiet. I was hastily summoned on the night of the 6th of January, being informed by the messenger that she had been doing some light work. On arrival I found her in complete collapse, the heart pounding tumultuously, with no pulse at the wrist, the face pale, and with an anxious expression. The respiration was rapid, and there was every indication of impending dissolution. I gave at once a hypodermatic injection of brandy and digitalis, ordering hot-water bottles to the extremities, and commenced the administration of chloroform, upon which color very soon began to return to the face, the heart became less tumultuous, the pulse returned to the wrist, and the patient began to show signs of consciousness, and noticed things; and in the course of an hour we were able to give by the mouth brandy, ammonium carbonate, and digitalis. I remained with her all night. She had three slight attacks of syncope during that time, when chloroform was again given, and was always followed by amelioration of the distressing symptoms. The tumultuous and angry heart would at once become more quiet and regular. In none of the later attacks did she become unconscious.

I saw her several times on the 26th, continued the treatment, and the nurse was instructed to administer chloroform when syncope threatened. She rested comfortably during the day, having two or three slight faining spells, but was generally better. The pulse was 120, respiration 30, temperature 99°, and the obstinate nausea was controlled by morphine and atropine. Nutritive enemata were advised, the brandy, ammonium carbonate, and digitalis continued. On the morning of the 27th the nurse said that the woman had slept some during the night, had had only one attack of fainting; the pulse was 126, the respiration 32, the temperature 99°. At this time she complained of a good deal of nausea and dyspnea. She said that she had felt no motion for two or three days. I found the os dilated, easily admitting two fingers. There was a vertex presentation, but no evidence of fetal life existed. I advised continuation of the remedies during the day. Her condition in the evening was less satisfactory; the pulse was weaker, 130; there was marked dyspnea; the respiration was 40, the temperature 99.8°. She complained of pain through the back. The nurse said that she had had slight chills during the day. The os was now dilated two inches, the cervix soft and yielding. I called again in about two hours. The pains had increased in the meantime and were unmistakably uterine. Hypodermatic injections of digitalis and strychnine were repeated every two hours. I now began administering chloroform, but not at any time in quantities to produce full anesthesia. Under its influence I hastened dilatation of the cervix, and when sufficiently dilated I applied forceps and delivered a female child that had been dead for several days. Once or twice during these maneuvers I was obliged to stop, on account of the patient fainting. Although extreme prostration followed, she gradually rallied under treatment. The convalescence from about the 10th day continued satisfactorily, and the patient was able to be about and attend to household duties in about six weeks.

Both cases had had attacks of rheumatism in childhood, but were not aware of any cardiac lesion.

It was said of the first case that she had suspected heart-disease, and had said that she would not allow herself to be examined for that trouble. I did not on my first visit examine the heart, though I should have done so. "Experience sometimes teaches dear lessons." It does not matter what the condition of the pregnant woman may be, or at what period he is called, the physician ought always to examine the heart and thus be prepared for any emergency, or indeed, if possible, to prevent an emergency likely to occur. I was dissuaded by the assurance that she had no such trouble, attributing her prostration to lack of sleep and to the obstinate vomiting. The cases of Sir Andrew Clark sufficiently prove the fallacy of accepting the statements of patients.

I believe that the only safe treatment prior to the fifth month in cases in which mitral stenosis is present, is in producing abortion. Dr. Mann fully concurred in this opinion. In both cases there was no impairment of health before the sixth month. It is at this time that heart-weakness begins. If the pregnancy is allowed to proceed, the chances are that the fetus will not survive the last two months. Children whose mothers are the victims of cardiac disease are often imperfectly developed, and are predisposed to untimely death.

The salutary effects of chloroform cautiously administered, especial care being taken not to push it to full anesthesia, were most perceptible. In both cases the pulse was at times small in volume, feeble in force, and irregular in rhythm; respiration was irregular, the heart tumultuous in action. Under the chloroform-stimulus the pulse would reappear at the wrist and color return to the face. While these effects were temporary, it gave opportunity to apply other and more permanent medication.

In closing, let me say that:

1. In all cases of pregnancy the physician should make a thorough examination of the heart at the first visit.

2. If mitral stenosis is present, and is recognized before the fifth month, the only safe treatment is in producing abortion.

3. If the sixth month has passed, the patient must remain perfectly at rest. The secretions must be closely watched, the husband or nurse instructed in the use of chloroform, and the patient must be under the constant care of a physician.

CLINICAL MEMORANDA.

OBSTRUCTION OF THE BOWEL FROM MECKEL'S DIVERTICULUM—A CHOLECYSTOTOMY.

BY J. A. PRINCE, M.D.,
OF SPRINGFIELD, ILL.

ON the 17th of last March, Bertha P., aged four years and three months, while putting on her clothes, was suddenly seized with acute lancinating pains, referred to the umbilicus. For three days previously she had complained of occasional pain in this region. Obstruction of the bowels soon became manifest, and was complete. On March 23d, I was called by the attending physicians, Drs. Mudd, of Athens, and Williamson, of Cantrall, to operate. Drs. S. M. Stocker, of Duluth, Minn., and N. S. Penick, of this city, accompanied me.

Her physicians stated that every means known had been employed to produce an action of the bowels, but without success. Opiates had been freely administered to control pain, which had been constant and excessive. During the three days preceding my visit, stercoraceous vomiting had been present. The temperature had ranged from normal to 100.5°, and the pulse from 108 to 137. The abdomen was tympanitic and tense, though not greatly distended.

One inch to the left of the umbilicus was an indurated area about two inches in its vertical diameter, by an inch and a half in its transverse diameter. Pressure over this area caused pain. A diagnosis of intussusception was made, and operation was advised. I explained to the parents and friends the dangers of the operation, and the almost certain prospect of a fatal termination without surgical interference. The proposal was accepted, and I proceeded without delay. An incision was made in the median line, and upon opening the peritoneum a large amount of thin fecal fluid gushed out. The abdominal cavity was carefully cleansed by flushing with hot sterilized water. The point of obstruction at once came into view, and was found to be due to an encircling band, the tension of which was so great that it had accomplished an almost complete resection of the incarcerated loop, the distal end being entirely cut through, and the proximal end nearly so.

The resection of the loop was completed, the ends freshened, and an end-to-end approximation made; the abdomen was flushed, drained, and the wound closed. The operation occupied one hour. Death occurred two hours later, from shock.

As the condition of the patient was very bad during the operation, and we were compelled to work by the feeble light of a kerosene lamp, all haste possible was made, and the seat of the obstruction was not noted, nor was the character of the band ascertained until the specimen was examined at leisure.

The resected loop measured four inches, and was from the lower portion of the ileum, though its exact distance from the cecum was not noted. From the side of the gut-wall projected a diverticulum of globular shape, one-quarter of an inch in diameter at its junction with the intestine; five-eighths of an inch in its greatest diameter, and one and a half inches long, ending in an elongated cord or band, which was impervious. The length of this band can only be estimated at about an inch, as it was broken in liberating the intestine, leaving one-half of an inch of its length attached to the diverticulum. This elongation was attached to the mesentery below the origin of the diverticulum, forming the incarcerating ring.

Meckel's diverticulum is rarely found to have this form, it being usually of a conical shape with its greatest diameter at its origin. Indeed, Treves says: "In no case, so far as I am aware, has it been seen to assume a polypoid form and present a comparatively narrow attachment." The cut shows well the diverticulum and its attachment.

The literature of this subject is very meager, the best descriptions that I have been able to find being in *Heath's Dictionary of Practical Surgery*, and Treves's little book on *Intestinal Obstruction*. *Quain's Anatomy* merely mentions the fact that a pouch or diverticulum may sometimes exist at a point in the lower ileum. To Treves I am indebted for the following description and facts:

Meckel's diverticulum is due to the persistence of the vitelline duct. When met with in its most perfect condi-

tion it exists as a tube, having a structure similar to that of the small intestine itself, that extends between the lower part of the ileum and the umbilicus. The length of this tube is, on an average, three inches. Sometimes it exists only as a nipple-like projection. On the other hand, cases are recorded in which the diverticulum, in the form of a free tube, attained the length of ten inches. The diverticulum is always single, and arises from the ileum, from one to three feet above the ileo-cecal valve.

In the majority of cases the end of the diverticulum is free. Very often, however, it is continued in the form of a solid cord. This diverticular ligament may break from its attachment to the parietes, and may float free within the abdominal cavity. Under such circumstances, however, it is much more usual for it to acquire fresh adhesions to some point of the peritoneal surface. These secondary adhesions of a free diverticulum, or of a diverticular cord at the extremity of one of the processes, are of considerable importance in the etiology of strangulation of the intestine. This secondary attachment is most often to the mesentery.

In twenty-three cases collected by Cazin, and nineteen by Treves, the attachments were as follows:

Near the umbilicus	10
" inguinal ring	1
" femoral ring	1
To the small gut	9
" cecum	3
" colon	1
" mesentery	17

CHOLECYSTOTOMY.

Mrs. D., aged thirty-nine years, was sent to me through the courtesy of Dr. Hobbs, of Mound Station, Ill. During the last four years the patient has suffered intensely from repeated attacks of biliary colic. Her physician found calculi in the stools after several of the attacks. When first seen by me, June 2, 1892, she was intensely jaundiced and greatly emaciated from much suffering. The attacks of colic were occurring as often as every week, and accompanied by a severe rigor, followed by high temperature, reaching 102° and 103°; the jaundice had of late been constant. I was unable to find calculi in the stools following attacks, after careful examinations repeated several times. As she was rapidly losing ground, and was in every way miserable, she readily consented to an operation, which was performed July 3d.

An incision four inches in length was made parallel to the lower margin of the liver, and over the gall-bladder, which could be indistinctly palpated; dense adhesions were encountered between the gall-bladder and the neighboring intestines, which were separated. The organ was much distended and contained calculi. It was sutured to the margin of the wound, and five days later was opened. Quite a quantity of clear, viscid fluid escaped, and about twenty-four calculi were removed. An attempt at this time to pass a probe into the duct failed; the orifice of the duct seemed to be completely closed. No bile whatever escaped from the bladder; during the healing process there was only the same clear fluid found on first opening the viscus. The discharge of this character, however, was quite profuse.

In four weeks she left the sanitarium, and two weeks later the fistula had completely closed. For ten weeks following the operation she improved rapidly in health; she was free from pain, and the jaundice entirely disappeared. Then the old attacks returned, seemingly with even greater severity; she returned to me September 23d. Her jaundice had returned and her general health was much worse.

Recognizing that there must exist an obstruction below the gall-bladder, a second operation was advised, and carried out September 26th. One calculus was found in the gall-bladder, which, as before, contained only clear fluid. Upon careful examination a rounded body, as large as a good-sized marble, was found deep down under the surface of the liver; this was movable to a very limited degree. Crushing was attempted, first with the fingers and then with instruments, but for fear of doing damage to the tissues the attempt was abandoned. The duct was finally incised and the large calculus extracted with forceps. The wound in the duct was closed as securely as possible with a continuous fine silk suture. As the gall-bladder was somewhat mutilated, and evidently useless, it was excised, and the wound packed with iodoform-gauze. On the second day after the operation bile began to drain up through the gauze packing, and though the dressings were frequently changed, the clothing and bedding were often saturated. The wound healed rapidly, and at the end of four weeks had entirely closed, and she returned home. At this time (December 15th) she has remained free from any return of her trouble.

The calculus in this case must have been located in the cystic duct, completely closing it, and encroaching on the common duct to such an extent as to almost completely close it. During the first operation it was probably drawn back somewhat from the common duct by the manipulation upon the gall-bladder, allowing the free flow of bile. The weight of the calculus was thirty-eight grains.

JAMBUL IN THE TREATMENT OF DIABETES MELLITUS.

BY V. E. LAWRENCE, M.D.,
OF HALSTEAD, KANSAS.

IN July, 1891, Mrs. L., widow, aged about sixty, presented herself, relating that for several months she had gradually been declining in weight and strength. Her tongue was moist and covered with a white coat; the saliva was frothy and slightly viscid. The skin, as she herself remarked, was dry and rough, and she complained of almost constant itching, especially marked in the vulvar region. The appetite was fair, but the digestion poor. She was fond of sweets. There was slight swelling about the ankles. Inquiry elicited the fact that about sixteen pints of urine were passed in twenty-four hours. About an equal quantity of water was drunk. An an examination of the urine disclosed the presence of abundance of sugar. The specific gravity was about 1035.

The diagnosis being clear, the question of treatment presented itself. I explained to the patient the nature of her disorder, and wrote out for her the usual bill of fare used by diabetics, strictly prohibiting all articles of food likely to be deleterious. As to medicines, the

usual remedies were employed. Directions as to diet and treatment were faithfully followed. The patient improved somewhat. The amount of urine passed was smaller and the thirst was less annoying, but considerable inconvenience was experienced in regard to the restricted diet. While the urine was diminished in quantity, the specific gravity remained unchanged or rose, and the percentage of sugar remained unchanged. This treatment was followed for several months, when I became convinced that my patient would probably not receive any material benefit from the usual remedies and that the final issue of her trouble would be death.

I now determined to use jambul. All other medicine was discontinued, and the use of the jambul was commenced in about eight-drop doses of the fluid extract. The patient was directed to still persist in the avoidance of all articles of diet containing starch or sugar.

As the patient lived some miles in the country I did not see her again for about two weeks, when she returned to my office saying that she was much improved; that the quantity of water passed was much smaller; and that nearly all of the unpleasant symptoms had either disappeared or so diminished that she felt comparatively comfortable. She had become more fleshy, but desired very much to return to her usual articles of diet.

As a number of cases had been reported in which patients, even in the advanced stage of the disease, had been cured when little attention was given to the food eaten, I concluded to allow her to choose her own articles of diet. With this change, the treatment was continued. After two weeks she again returned, with the report that she still grew better and that the change of diet did not seem to be injurious, and that she ate starches as she wished, but was somewhat careful as to sugar.

An examination of the urine disclosed the presence of but a trace of sugar; and, later, even this disappeared. The patient continued the jambul for some weeks longer and then did not return. Since then I have seen her several times. She reports herself well and no longer has any symptoms of diabetes.

MEDICAL PROGRESS.

The Parasitism of Carcinoma.—METSCHNIKOFF (*British Medical Journal*, No. 1667, p. 1273) adduces evidence and presents argument in support of the close analogy between the coccidiosis of rabbits and carcinoma in man. He points out that in the livers of rabbits there are often present grayish or white nodules, with puriform contents, in which are found oval bodies known as coccidia—low forms of animal organisms. In young rabbits the presence of these lesions engenders a disease that often proves fatal, while full-grown rabbits tolerate the parasitism without suffering great harm. This disease, though infectious and parasitic, is never transmitted by true contagion. The nodules in the liver are formed by abundant vegetations of the biliary ducts, and are true tumors. The coccidiosis of rabbits is a miasmatic affection. In order to produce the disease in other rabbits the coccidia must undergo a certain transformation and segmentation. That coccidian infection occurs in man is demonstrated by the discovery of the parasite of malaria. Like the coccidiosis of rabbits and like malaria, carcinoma presents miasmatic characters. It was the presence of epithelial proliferation in both the coccidiosis of rabbits and carcinoma in man that suggested the parasitism of carcinoma. Numerous observers have found in various forms of carcinoma cellular bodies presenting none of the appearances of degeneration of protoplasm or of nuclei. Careful examination disclosed a close resemblance between these bodies and the coccidia of the rabbit. The absence of contagious characters from coccidiosis and carcinoma may be ascribed to their miasmatic properties, the spores of the parasite being formed outside of the organism.

PLIMMER (*British Medical Journal*, No. 1667, p. 1277) reports the examination of specimens from thirteen cases of recent carcinoma, prepared specially, and also fifty-three specimens from thirty-seven cases of various forms of carcinoma, prepared in the ordinary way, and the finding of the specific parasite in all. The organisms were most abundant near the growing edge of the neoplasm and in the glands that had become secondarily affected; they were present in small numbers or not at all in parts of the growth that were undergoing degeneration; they were also wanting in the fibrous portions of the growth and in cells undergoing karyokinesis. The bodies were nearly quite round and possessed nuclei and capsules. There was evidence of the ameboid nature of the organism. The organisms were best demonstrated by first placing small pieces of perfectly fresh tissue for twenty-four hours in a solution made just before using, and containing equal parts of a 5 per cent. solution of potassium bichromate, and a saturated solution of mercuric chloride in a 0.75 per cent. salt solution; then washing in running water for twenty-four hours, and then successively placing them in 30 per cent. alcohol for twenty-four hours; in 60 per cent. alcohol for twenty-four hours; in 90 per cent. alcohol for twenty-four hours; when they were thrown into absolute alcohol until they were hardened. They were then imbedded in paraffin, cut and stained on the slide with the Ehrlich-Biondi triple stain, washed out with alcohol, cleared with xylol, and mounted in xylol-balsam.

Two Pubeotomies.—TÖRNGREN (*Centralbl. f. Gynäkologie*, No. 49, 1892, p. 953) has reported the case of a woman, forty years old, pregnant for the ninth time, and having a generally contracted pelvis, in which pubeotomy was performed. The first four children had been born spontaneously; the second child was born dead; the fourth weighed 6¼ pounds. In the fifth labor version was performed, but the child was born dead, weighing 8 pounds. In the sixth labor, also, version was performed; there was some difficulty in delivering the head; the forceps was applied and withdrawn; the child weighed 7¾ pounds, and lived. The seventh child was born spontaneously, and weighed 6¾ pounds. In the eighth labor, version was performed, but the child died. The maternal measurements were as follows: Between the iliac spines, 8.27 inches; between the iliac crests, 10.39; between the trochanters, 10.97; Baudelocque's diameter, 6.73; diagonal conjugate, 3.92; true conjugate, 3.15. The vertex presented; the lesser fontanel to the right; the

sagittal suture in the transverse diameter. Pubeotomy was performed, and the child was safely delivered by means of axis-traction forceps. The fetal diameters were as follows: B. P., 3.65 inches; B. T., 3.08; O. F., 4.23; O. M., 5; S. B., 40.4. The child was 20 inches long, and weighed 6¼ pounds. The mother died twenty-two hours after the operation, in collapse. The post-mortem examination disclosed the existence of fatty heart, with hypertrophy of the right side; pulmonary emphysema; bronchitis; chronic nephritis. The second case occurred in a woman, thirty-six years old, pregnant for the second time, basiotripsy having been required in the first labor on account of a generally contracted pelvis. The pelvic measurements were as follows: Between the iliac spines, 8.85 inches; between the iliac crests, 10.39; between the trochanters, 11.55; Baudelocque's diameter, 6.16; diagonal conjugate, 3.65; true conjugate, 2.96. The vertex presented; the lesser fontanel to the left; the sagittal suture in the transverse diameter. The child was safely delivered by means of axis-traction forceps. The fetal diameters were as follows: B. P., 3.65 inches; B. T., 3.08; O. F., 4.62; O. M., 5; S. B., 4.23. The child was 20½ inches long, and weighed 7½ pounds. The woman got up on the twenty-first day.

Intubation.—BALL (*Lancet*, No. 3613, p. 1216) has reported twenty-two cases of intubation in children of from thirteen months to eight years old, with ten recoveries. The operation was performed in every case for the relief of symptoms of laryngeal obstruction, which threatened the life of the child, and as the alternative of tracheotomy. In one case the obstruction was a result of the swallowing of hot tea; in another, of swallowing carbolic acid. The others were cases of laryngitis, simple or membranous (diphtheritic); it was not always possible to determine which. In five cases the condition was secondary to measles; four of these died. In seven cases tracheotomy was performed after intubation had been tried, principally because the tube seemed to be obstructed by membrane or secretions; in all of these, death took place. In all the cases in which recovery took place the tube was left in the larynx for periods varying from three to thirteen days, the average period for the ten cases being eight days. In four cases the thread was permitted to remain *in situ*; in one of these the child removed the tube by means of the thread. In the remaining cases the thread was removed immediately after the introduction of the tube. In each of two of the fatal cases an ulcer was found on the anterior wall of the trachea, at a point corresponding with the lower extremity of the tube. The tubes, however, were not of exactly the same design as the O'Dwyer tubes. In one case death took place during the operation.

THERAPEUTIC NOTES.

Enormous Doses of Paraldehyde in a Case of Acute Mania.—At a recent meeting of the New York Neurological Society, DR. WILLIAM D. GRANGER reported the case of an unmarried woman, twenty years old, in a second attack of acute mania that had existed for six months. The previous attack had occurred five years before, and was fully recovered from. There was a history of insanity in her father's family, and her mother was a "nervous" woman. The attack was of great violence, and attended with pronounced delusions and hallucinations. There was marked insomnia from the first. During her previous illness she was given large doses of paraldehyde, and with the advent of the first symptoms of the second attack, the same drug was administered. She was given each night ten fluiddrams of paraldehyde, in divided doses, and this method of treatment had been kept up for nearly four months. It produced but little sleep, and that was broken. When the patient came under Dr. Granger's care, he found that in spite of her close confinement and the enormous doses of paraldehyde that she was taking, she was showing some evidence of convalescence. She was well nourished and had a good appetite. There was no gastro-intestinal trouble. She had no cutaneous eruption. A careful examination failed to reveal any unfavorable symptoms connected with the use of the drug, unless it was that it had lost some of its hypnotic power. After the third night, and against the wishes of the family, Dr. Granger determined to rapidly withdraw the drug, and he did so in ten days. After its withdrawal the patient was able to sleep soundly all night. No other drug was substituted. She suffered no inconvenience during the period of its withdrawal. In three months the patient was discharged, and she became perfectly well. No symptoms of the paraldehyde "habit" appeared.

The Treatment of Cholera with Anticholerin.—At a meeting of the Society of Physicians of Budapest, ANGYAN (*Prager medicin. Wochenschr.*, 1892, No. 49, p. 606) reported the results of the employment of anticholerin in nineteen cases of cholera of unusually severe type. Nine of the cases died—a mortality of 52 per cent. It was found that the remedy exerted a most beneficial influence upon the course of the disease. In some cases slight transient febrile reaction appeared. Most of the symptoms soon changed for the better, diarrhea and vomiting ceasing on the first or, latest, on the second day. Cyanosis, which would sometimes yield to hypodermatoclysis, frequently, however, to recur, disappeared permanently after the employment of anticholerin. The secretion of urine was resumed under the influence of the treatment, and soon attained respectable proportions; while in algid cases not treated with anticholerin the anuria would persist for three or four days. Although the number of cases was too small to lead to a final conclusion, the general impression was a favorable one.

THE MECHANISM OF ANESTHESIA.

IT is, no doubt, a matter of considerable interest, if not importance, to determine in what manner anesthesia takes place—in short, to demonstrate the mechanism of it, or if we cannot go so deeply, to have some theory, which, if it does not explain all the facts, at least serves to point out the way toward something better.

To demonstrate the mechanism of anesthesia—to show both the causation and progression of the phenomena, and their dependence upon one another, in obedience to definite laws—is an august problem. Many have attempted to solve it, and in many ways. Some, relying on their great experience and practical knowledge, gained by extensive observation of the effects of anesthetics in surgical cases, construct a theory with these data alone. Others again, not neglecting these data, make them supplementary to a process of reasoning on the more pregnant facts of experimental physiology. To speculations of the latter kind we desire to direct the reader's attention, though we must observe that, much as these speculations are to be prized as real advances, they appear to us to fall short of the truth by ignoring a third series of facts—namely, the facts of psychology.

To CLAUDE BERNARD,[1] perhaps, more than to any other, we owe our present knowledge on this curious subject. It was he that first developed, in a series of incomparable experiments, the surprising range of the anesthetic powers of ether and chloroform. Not alone animals, but also plants, the germinating ovule, the simplest of all organisms, the protozoa—in short, any organic body with protoplasm for its basis, may be anesthetized.

Protoplasm itself may be anesthetized, and on this depends the all but universal anesthetic power of ether and chloroform; for protoplasm is the basis of all life—is the fundamental living element of all tissues. On protoplasm ether and chloroform act by suspending vital activity, or, to speak differently, by suspending the power of reacting to stimuli. This is anesthesia in its simplest form. It is the first stage in the action of these anesthetics on protoplasm—a point of some importance, for there is in this case, as in more highly organized bodies, a second and deeper stage in which the vital activity, the power to react to stimuli, is destroyed without possibility of renewal.

The nature of anesthesia in man is not much different. In man, as in simpler organisms, it is the protoplasm that is attacked. We extract from BERNARD a passage bearing on this point: "If we reduce a man to insensibility—for example, by means of ether or chloroform—we find that the anesthetic, on being breathed, is absorbed by the lungs and circulates in the blood. It is first upon the delicate protoplasm of the nervous centers that the anesthetic exerts its influence, whence, indeed, it happens that the phenomena of consciousness and perception by the senses are the first to disappear, although the protoplasm of the nerves, the muscles, the glands, and other anatomic elements is not affected. This explains why, during anesthesia, the functions of life are able to continue, and this also explains why anesthesia in this stage is not perilous to life; for if, at the same time, we should reduce the protoplasm of all of the anatomic elements to a state of anesthesia, the functions would simultaneously cease their activity and death would be instantaneous."[1]

How, then, may we describe the changes that occur in protoplasm during anesthesia? How is the irritability of tissues or of the elements of tissues suspended by an anesthetic? Possibly, because some chemical or molecular change is induced (BÖTTGER). This, as PROF. SCHMIEDEBERG remarks, is no explana-

[1] See his book entitled Phénomènes de la Vie, vol. i, p. 251.

[1] Op. cit., p. 254.

tion at all. A better and more definite explanation is one that appears to be gaining ground and has had the support of BERNARD, BINZ, and POHL, that these changes, chemical or molecular, are a phenomenon of coagulation.

To such a theory the recent researches of POHL lend some support. From them it appears that chloroform—which he selects for experiment—is never present in the blood in a quantity greater than 0.01 per cent., and that on the average the quantity is not greater than 0.035 per cent.—a fact that serves to explain why the vital activity of the protoplasm of the nervous centers is suspended (a suspension that we have seen really takes place in simpler protoplasm and constitutes true anesthesia), but not destroyed. It is further worthy of remark, that in cases of death from chloroform, POHL found always a higher percentage in the blood than at other times. Are there, however, any facts to show that chloroform does exert its influence upon the nerve-centers first, and on them more powerfully than on other portions of the body? It may be answered, Yes, with some slight qualification that is not material.

POHL found that in the blood chloroform was taken up chiefly by the lecithin and cholesterin, for which it manifests a strong affinity; that it accumulated in those parts of the body that are rich in these substances—in the brain more especially; that the serum held very little, an exceedingly small amount indeed. It is this tendency of chloroform to enter rapidly into combination with lecithin and cholesterin, and therefore to make its way rapidly to the brain—the organ richest in these constituents, that supports the views already mentioned. But it is, perhaps, unfortunate for a theory that professes to explain anesthesia by supposing some specific action of chloroform on the nerve-centers, and particularly the ganglion-cells, that these are not richer than many others, as, for example, liver-cells, in those substances that have an affinity for chloroform.

We cannot, POHL says, with propriety speak of anesthesia of liver-cells. That this is, nevertheless, not an objection of very great weight is manifest if it be recalled that it is not the function of the cell, or any accidental properties belonging to the cell, that render it capable of anesthesia, but its having protoplasm for a basis. We cannot, to be sure, abolish the faculties of perception and sensation of a liver-cell, but these faculties are not essential to anesthesia, except in so far as they are inherent in protoplasm; for anesthesia is finally that state of protoplasm in which its vital power—its power to react to stimuli—is suspended, but not destroyed.

We have said that the present speculations fall short of the truth because they ignore or treat but very partially the facts of psychology. Has it never occurred to the advocates of the theory just described to consider the phenomena from the psychologic point of view as well? Have they never reflected on the number and nature of those changes that take place when consciousness is lost? Is but one part of the brain concerned when there is successively loss of perception, loss of sensation, loss of the power of forming judgments, loss of will, and finally complete loss of intelligence, or is there something more concerned? The matter, we are sure, requires careful analysis, and we trust someone will come forward who is capable of it.

Besides, it may be urged against this partial view of the nature of anesthesia, that some anesthetics act differently than do others; and though it may be true of chloroform that in the course of its action on man consciousness and perception by the senses are affected first, it is not true of another anesthetic, ethyl bromid. We extract from VON ZIEMACKI'S paper on ethyl bromid a valuable passage that makes this clear—a passage that shows so well, besides, that anesthesia, as it ought to be conceived, is something more than local or general insensibility to pain.

After describing the preliminary effects of ethyl bromid, redness and tingling of the skin, etc., VON ZIEMACKI continues: "In this stage (the second) sensation was practically abolished, but *intelligence was unimpaired.* I heard and understood perfectly the conversation of my colleagues about me; and I recollect with great vividness that the feeling of taste was unaffected, though at the same time I felt no longer the pain of a puncture of the nose. Sensibility to pain, in fact, was from this time completely suspended. I understood easily that the puncture of the nose must be painful, yet I felt only the *sense of contact, not the pain*, which is a very striking fact. Next, there was darkness before the eyes. . . . Unconsciousness, I maintain, surpervened very rapidly."

From this, it is clear that sensation was lost before perception, and perception before consciousness. Last came unconsciousness. In the stage before that, in the intermediate stage between the loss of perception and the loss of consciousness, there was

no true anesthesia, for the mind was still free, and hence a puncture was felt, but not the pain accompanying it.

With these facts before us, it appears to us inconceivable that the theory of "specific action on the ganglion-cells" is a sound explanation of anesthesia; for that is a theory that seems to demand something invariable in the order of the phenomena, some function, besides, which has no ground for existing in the ganglion-cells themselves.

A TRUE PHYSICIAN.

THE advice as to the prophylaxis of venereal disease that individuals calling themselves physicians have dared to give, and that journals assuming to represent the therapeutic status of the day have dared to publish, has on previous occasions been discussed in these columns. It is with a deep feeling of gratitude to the manly author that we now quote advice upon the same subject—but far different in spirit—from the reprint just issued of GOWERS'S Lettsomian Lectures of 1890, "On Syphilis and the Nervous System."

"One means alone remains, old as the malady itself, by which it can be prevented. One method, and one alone is possible, is sure, and that one is open to all. It is the certain prevention secured by unbroken chastity. . . . Do we do all we can—and our profession gives us power that no other has—do we do all we can to promote that perfect chastity which alone can save from this and from that which is worse? The opinions that on pseudo-physiological grounds suggest or permit unchastity are absolutely false. . . . They rest only on sensory illusions, one of the many illustrations of a maxim I have often to impress on various sufferers, 'There are no liars like our own sensations.' Rather, I should say, they rest on misinterpretations of these, always biased and often deliberate. With all the force that any knowledge I possess and any authority I have can give, I assert that no man ever yet was in the slightest degree or way the worse for continence or the better for incontinence. From the latter all are worse morally, a clear majority are worse physically, and to no small number the result is and ever will be utter physical shipwreck. . . . Let us then, with our power for good or evil, beware lest we ever give even a silent sanction to that against which, I am sure, on even the lowest grounds that we can take, we should resolutely set our face and raise our voice."

These are the words of the true physician, and again let us express our thankfulness that even in this age of demoralizing competition for wealth, popularity, and the influence that may be gained by "saying of evil 'it is good,' and of good 'it is evil,'" one teacher at least has the wisdom to see the truth and the courage to speak it.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, December 28, 1892.

DR. J. M. BALDY read a paper entitled "Gynecological Technique as Carried Out at the Gynecean Hospital."

He stated that the watchwords from the beginning to the end of an operation are *thoroughness* and *simplicity*.

The preparation of the patient should begin, when possible, at least twenty-four hours before the operation. The first steps are to regulate the diet and empty the gastro-intestinal tract. Free purgation is begun at once, preferably by the use of magnesium sulfate, a dram dissolved in water, every hour until the bowels begin to move. Usually five or six doses are sufficient to accomplish the object. The purgative should be so administered that the action of the bowels ceases five or six hours before the time set for the operation. After beginning the administration of the purgative, the diet should be light and concentrated. If the operation is to be performed in the afternoon, the patient's supper on the day before consists of the ordinary house-diet. From this time on nothing passes her lips, unless it be a glass of milk or a cup of bouillon at breakfast-time. Even water, except in small quantities, is withheld. These steps in the preparation can be carried out in the case of most patients, but in dealing with an unusually weak woman, considerable judgment must be used.

A hot bath is given on both the day before and the morning of the operation. If the patient is unable to be moved to the bathtub, the patient is bathed in bed. Prior to the final bath an enema of soapsuds and water and a vaginal douche of mercuric chlorid (1 to 3000) are given. Immediately on coming from the bath a fresh night-gown is put upon the patient and she is placed in a bed specially prepared for her reception. After returning to bed the abdomen—the seat of the operation—is specially prepared. A nail-brush, soap and hot water are used freely and vigorously, special attention being paid to the umbilicus and the pubic hairs. In exceptional cases the pubes is shaved. The abdomen is then bathed with alcohol and turpentine and is finally protected until the time of the operation with a towel wrung out of mercurial solution.

When the patient is placed on the operating-table the abdomen is well rubbed with ether and bathed with alcohol by the operator as the final preparation, especial attention being paid to the pubic hairs and the umbilicus. The legs are wrapped in a blanket, which extends from the feet to the pubes; a second blanket is placed over the chest. All blankets, clothing, table, etc., about the patient, from her chest to her feet, are now covered with towels prepared for the purpose, the abdomen being left bare from the epigastrium to the pubes. Over all this is placed a piece of mercurial gauze, with a slit in it at the point selected for the incision.

All tables used in the operating-room, with the exception of the Krug frame for Trendelenburg's position (which is of galvanized iron), are made of wood, perfectly plain, and shellacked. The reason for this is twofold—first, because it is desirable in the preparation of the room that it should be emptied; this is rendered

possible in the case of everything except the gas-fixture and the sink. Secondly, as there is an operating-room on each floor, it becomes necessary to frequently move the tables from one room to the other. When the rooms are not in use, the windows are always open. The walls of the room from floor to ceiling are of white tile; the window trimmings are of white marble; the floors are of asphalt; the ceilings are plastered and heavily painted. In the preparation, the room is first stripped of all of its furniture. The walls, ceiling, and floor are washed by means of a hose, and then mopped with a cloth dipped in mercurial solution. As each article is brought into the room it is scrubbed with soap and water, rinsed off, mopped with mercurial solution, and placed in its proper position; the tables and benches are covered with sheets or towels specially prepared for this purpose. All linen used in the operating-room has been separately laundered. Distilled water is used throughout the operation.

After an operation the instruments are thoroughly scrubbed with soap and water, and are then passed through scalding water before being returned to the case. Prior to the operation they are boiled for twenty minutes in a weak solution of sodium bicarbonate. As few instruments as possible are used. In an ordinary operation, two needles, two ligature-staffs, four hemostatic forceps, a knife, a needle-holder, and a pair of scissors are amply sufficient. These are taken, together with the tray on which they are placed for boiling, directly from the sterilizer, and put upon the table as the patient is brought into the room. In this way they are not handled from the time at which they are taken out of the sterilizer until they are to be used.

Three varieties of ligatures are employed: silk, silkworm-gut, and catgut. A half-hour before the operation the silk is immersed in a solution of mercuric chloride (1 to 100); prior to being used it is washed in boiling water. The silkworm-gut is boiled with the instruments. The catgut is prepared by being immersed in ether for forty-eight hours, soaked for the same length of time in a 1 to 100 alcoholic solution of mercuric chlorid, after which it is put in a solution of two parts of oil of juniper and one part of alcohol. It is taken directly from the latter solution for use at the operation.

All sutures and ligatures used within the abdominal cavity are of silk (Chinese twist). Silkworm-gut is invariably used for closing the abdominal wound. Catgut is used principally in vaginal hysterectomy and plastic work.

New sponges are prepared by being thoroughly beaten, soaked for twenty-four hours in a weak solution (3 per cent.) of hydrochloric acid, after which they are soaked for twenty-four hours in a strong solution of sodium bicarbonate, and are finally placed in alcohol. Immediately after being used in an operation they are thoroughly washed in cold water, placed in a strong (practically saturated) solution of sodium bicarbonate for twenty-four hours, at the end of which time they are removed, washed under the cold-water spigot until all of the sodium salt is washed away, and are then immersed in a solution of sulphurous acid for twenty-four hours. They are taken directly from the acid solution, washed, and placed in commercial alcohol until used. Four sponges only are used at each operation.

The dressing of the abdominal wound consists in placing several strips of dry mercurial gauze over the incision and a cotton pad covered with gauze over this, the whole being held in place by a six-tailed bandage. Dressings are not disturbed for eight days. No iodoform or other powder is used. Stitch-hole abscesses are exceptional.

After being used, the glass drainage-tubes are soaked in a strong solution of sodium bicarbonate for twenty-four hours, rinsed under the spigot, washed with turpentine and ether, and then boiled for twenty minutes, after which they are kept in commercial alcohol.

Rubber drainage-tube, whenever used, is soaked in mercurial solution, and washed in boiling water.

After an operation the drainage-tube is cleaned by the nurse every fifteen minutes or half-hour, as occasion requires. As the fluid discharged from the tube lessens in quantity, the intervals between cleaning are lengthened. Whenever the tube is cleaned the nurse's hands are carefully prepared with soap and water and mercurial solution.

At and after each cleaning the syringe used to withdraw the tube-contents is cleansed inside and out with hot water and mercurial solution, as are also the mouth of the tube and the rubber protecting it. Fresh mercurial cotton is placed over the entrance of the tube at each cleaning. The tube is removed as soon as the contents become clear and small in quantity. The edges of the opening left by the tube are drawn together by a strip of adhesive plaster, and the dressings replaced by fresh ones.

Everybody that takes part in an operation, and is liable during its performance to handle any of the instruments or materials, is required to go through the same preparation. All assistance is rendered by three nurses; the chief nurse assisting the operator directly, a second nurse attending to the sponges, and a third nurse changing the waters. The preparation of operator and nurses is as follows: a hot soap bath is taken, and clean linen clothing direct from the laundry is donned. The hands and arms are prepared by first carefully cleansing the nails with a penknife, followed by a free use of hot water, soap, and nail-brush for twenty minutes, and rinsing in fresh water. They are then bathed in commercial alcohol, and are finally soaked in a mercurial solution (1 to 2000) for five minutes. The greatest danger-point of infection is, of course, under the nails, and time used in a most careful hand toilet is never misspent —is, in fact, absolutely essential to success.

There is not an article in the operating-room that cannot be duplicated or easily substituted in almost any well-ordered household. Soap, water, nail-brush, and tablets of mercuric chlorid are easily obtained, and with a little time and trouble the poorest hovel can be turned into a good and safe operating-room. Of course, this means hard work for both nurse and surgeon, but what nurse or surgeon who has once experienced the horrors of a death from septic peritonitis would not feel that the work before the operation was as nothing in comparison with the results that follow.

The number of instruments, sponges, etc., may seem to many to be entirely inadequate for the purpose, but in many hundreds of operations they have been found amply sufficient; it is exceptional that recourse to the instrument-case has been necessary. The fewer articles

used the fewer sources of possible infection and accident. A large number of instruments lying about constitutes, in addition, a source of endless confusion and annoyance, and requires an extra assistant.

CORRESPONDENCE.

CHLOROFORM AND THE HEART.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of October 29, 1892, this passage occurs: "We have noted as instances of that frame of mind which is unsuitable for fair judgment such statements as Surgeon-Major Lawrie's, that 'the most important result of the labors of the Hyderabad Commission has undoubtedly been to establish the proof that chloroform has never under any circumstances whatever a direct action upon the human heart.'"

1. The expériments of the Hyderabad Commission have been confirmed by cross-circulation experiments, performed in Hyderabad during the last three months. They prove that chloroform has no direct action on the heart, and that the fall of blood-pressure, which is the normal condition of anesthesia with chloroform, is due to its action on the vasomotor center in the medulla oblongata. Narcosis of the vasomotor center causes dilatation of the small arteries, by which the fall of blood-pressure is brought about, and is one of the earliest, if not the very earliest, of the effects of chloroform. The passage of the blood from the arterial to the venous system is thus greatly facilitated, so that the work of the heart is lessened. Not only, therefore, has chloroform no direct action on the heart, but the heart is safeguarded from the commencement to the end of the administration, whether the anesthetic is given in medicinal or in poisonous doses. Moreover, unless the nutrition of the heart is interfered with by interference with the breathing, as, for example, by choking or by overdosing, the heart may safely be left to look after itself. The heart is, literally and in truth, the chloroformist's sheet-anchor, and his very best friend.

2. There is no such thing as a safe *method* of chloroform administration, and overdosing may take place in a variety of ways, whether the drug is given on lint or on a towel, or on a cap such as we use, or with Junker's or Skinner's, or any other form of inhaler. The one and only point of vital importance in the administration of chloform is that, whatever method be employed, the breathing shall never be interfered with in any way throughout the inhalation. If this condition is fulfilled, it is impossible to produce anything with chloroform but anesthesia, and anesthesia alone is entirely free from risk.

3. I am at a loss to understand why you should regard a frame of mind that is the outcome of twenty-six years' clinical experience, in England and in India, which accords with the foregoing facts in every particular, as "unsuitable for fair judgment."

4. I venture to submit, most respectfully, that this frame of mind is infinitely more suitable for fair judgment than the frame of mind of the writer of your article. Any evidence, however trumpery, is accepted by certain writers if only it favors the view that chloroform affects the heart directly; and they unhesitatingly reject without examination all evidence which goes to prove that it never does so.

5. The following statistics may be of service to you: Up to the end of November of this year I have notes of every event which took place during more than two thousand chloroform administrations in the Afzulgunge Hospital. There were two cases of narcosis of the respiratory center due to accidental overdosing. In one case the patient was saved by "secondary chloroform syncope"—one form of that reflex stoppage of the heart, which, according to the Glasgow committee, constitutes the chief danger under chloroform; and in the other by artificial respiration.

Your most obedient servant,

EDWARD LAWRIE,
Surgeon, Lieut.-Colonel.

THE RESIDENCY, HYDERABAD, DECCAN,
December 8, 1892.

[We inserted the passage that has given Dr. Lawrie perhaps just offence, assuredly from no want of respect for him, but merely because, in order to make our paper complete as a piece of criticism, we needed to give eminent examples of a bias, plainly discernible in nearly all the writings we examined, toward one anesthetic or another. We selected, we say, eminent examples. It would be invidious and harsh in such a case to do otherwise. Dr. Lawrie's experience with chloroform has been unrivalled for consistent and successful carrying out of sound teaching, and we are not inclined to depreciate it, as he seems to suppose. It is this experience constantly making itself felt in matters above it that we objected to. In abstract reasoning on the results of experimental science it is constantly working for evil, by transforming those results, by distorting them and giving them a large asseverative character, to the exclusion and prejudice of other facts that might be reconciled with them. Hence, the sentence in question, purged of this disturbing element, contains the truth, and Dr. Lawrie would write it so: that the "most important result of the labors of the Hyderabad Commission has undoubtedly been to establish the proof that under these circumstances chloroform never has a direct action on the heart;" but into his mind comes the recollection of his great and successful experience, and he writes "human heart" and "never under any circumstances whatever."[1] Thus the sentence comes to contain a truth and the implicit denial of another truth—a truth demonstrated by Laborde and François Franck, that chloroform acts mechanically, as indeed other volatile substances do on the terminal filaments of the nasal branches of the fifth nerve, and arrests *simultaneously* the heart and respiration—a stoppage that is nearly always temporary, but sometimes fatal (*arrêt cardio-respiratoire primitif*).[2] If this is a real danger, then sentences like Dr. Lawrie's tend to obscure it.

We are sorry that we have not space for a minute reply to the following passage from a postscript: "I

[1] There are passages in Dr. Lawrie's articles and printed correspondence in which he has spoken more carefully, seeming to admit the possibility of an accident if Syme's principles are neglected. See, for example, the Lancet, vol. i, 1891, p. 591.

[2] Bulletin de l'Académie de Médecine, 3me série, tome xxiii, pp. 556, 591, 613, 709, tome xxv, p. 816; Gazette hebdomadaire de Méd. et de Chir., 1876, pp. 773, 775; Archives de Physiologie norm. et path., 1889, p. 548; also, Du Bois-Raymond, Berliner klin. Wochenschrift, 1891, No. 53.

have never met with any case fit for an operation which was not fit for chloroform. This is the expression of one man, and must be taken for what it is worth."

This refers to our remark that some cases were fit for chloroform, some for ether, some for gas, etc. This statement, we believe, is true, and we made it because we thought it a pity that anyone should be prevented from using chloroform who can use it properly; and more particularly because we thought that the first step toward a sound course of instruction in the matter of anesthetics for students was to let each anesthetic have free play to establish any just claims.—Editor The Medical News.]

LABOR DELAYED BY RIGIDITY OF THE OS UTERI.

To the Editor of The Medical News,

Sir: In a recent article, Dr. Edward P. Davis (The Medical News, December 10, 1892, p. 656) truly says: "There is no more trying complication of labor for patient and physician than persistent rigidity of the os uteri"—a statement with which I fully coincide. In a case recently under my observation no surgical aid was required; in fact, in an experience of twenty years of active practice I have never had occasion to incise the cervix, for the reason that I have always accomplished dilatation by means of the fingers and Barnes's dilators, or by the ballon-Champetier, which I prefer in some cases, as it produces more rapid contractions; and in cases of hemorrhage from detachment of the placenta, it acts as an excellent intra-uterine tampon.

Mrs. A. B., thirty-two years old, a primipara, of good general development, rather robust, with a normal pelvis, was taken in labor on the night of November 21, 1892. As I was occupied with another case at the time, Dr. E. F. Smith attended the woman for me. On making a vaginal examination he found the cervix rigid and undilatable, although the pains were severe and frequent. As in the course of an hour no progress or change had taken place, he ordered a dose of chloral hydrate, gr. xx, to be repeated at the end of an hour, if no sleep had been secured. The pains persisted during the night, and about 6 o'clock A.M. the characteristic bearing-down pains had set in. The cervix was still unyielding. The patient had not derived much benefit from the chloral, on account of the persistent and severe pains which had continued during the whole night. I saw the patient this day at about 1 P.M. I found the cervix still rigid, but by manipulation succeeded in introducing my index-finger into the uterine cavity, and found a vertex-presentation in the right occipito-posterior position. The membranes had already ruptured spontaneously, but no amniotic liquid could be detected. By this time the patient's strength was failing, and as the bearing-down pains were severe and frequent, and a reasonable time had elapsed since labor had begun, without progressive dilatation, it was decided to promote this end by manual procedures until Barnes's smallest dilator could be introduced. This, however, was soon pushed down into the vagina by the strong uterine contractions, but was replaced immediately by the next larger size until finally the largest size was introduced. Sufficient dilatation had now been produced to admit the introduction of the forceps, which were applied without difficulty and without the use of an anesthetic. Gentle traction was made with each pain, and after some hard pulling delivery was accomplished without any accident or injury to the mother. Unfortunately the child, a well-developed boy, died shortly after being born, in spite of all efforts at resuscitation. A dose of ergot was given to the mother, and as the placenta did not come away, after waiting twenty minutes I had recourse to Crédé's method.

I do not advise or recommend the making of multiple incisions into the cervix. My experience has taught me that by the use of the fingers, Barnes's dilators, or the ballon-Champetier, dilatation can be effected without exposing the patient to septic infection by the use of the knife. Dr. Davis well says: "It is distinctly a dangerous method of treatment."

Respectfully, J. J. Lamadrid, M.D.

Brooklyn, N. Y.

POSSIBLE ABUSES IN PRIVATE HOSPITALS.

To the Editor of The Medical News,

Sir: A patient was admitted on December 3d to the Gynecological Ward of the Philadelphia Hospital with the following history: J. D., aged twenty-three years, had been perfectly healthy and free from pain until five weeks ago, when she had a fall, followed by severe pains in the groins and back. She was examined by an abdominal surgeon, who urged an immediate operation, to which she consented, and for which she entered the surgeon's private hospital. She does not know what was done to her, but she was very ill after the operation and suffered greatly. At the end of four weeks, although she was in a wretched condition, she was told she must leave the hospital, as it was against the rules to keep anyone longer than that time. She went to some friends, but as she was perfectly helpless and they could not attend to her, she was sent to the Philadelphia Hospital on the next day but one.

On examination, a large fistula was seen in the lower part of a scar upon the abdomen, discharging flakes and pus. The temperature was high, the pulse very rapid and feeble. It was plain that the patient had not long to live. Her life was a little prolonged by good treatment and nursing, but she died on December 26th. Now, if the woman's story was true—and I see no reason to doubt it—she had been ill-treated. The inference is unavoidable that she was turned out of the hospital in which she had been operated upon to save trouble, expense, and the operator's statistics. It was perfectly evident that she must die, and it was known, she declared, that there was no one to care for her. Had this occurred in a public hospital the managers would have called the surgeon to sharp account, but when one individual is owner, manager, and operator, he is at present absolutely irresponsible, and the temptation to do his patients wrong from interested motives may be strong. Would it not be a wise regulation that private hospitals should be licensed and regularly inspected by the authorities? On well-grounded complaint the license could be revoked. And would not a proposition to this effect come more gracefully from the profession itself?

It is better policy, surely, to suggest and provide safe-

guards ourselves against individual wrong-doing in our ranks that may sully the reputation of medical men as a class, rather than to have such measures forced upon us from outside. Very respectfully,

BARTON COOKE HIRST.

REDUCTION OF GOITER BY THE FARADIC CURRENT.

To the Editor of THE MEDICAL NEWS,

SIR: An article in THE MEDICAL NEWS of December 3, 1892, page 634, entitled "Reduction of Goiter by the Faradic Current," calls to mind a similar case of my own:

Miss P., fourteen years old, consulted me for a "large neck," which had been noticed first about one year previously. She was a strong, healthy girl, and experienced no inconvenience, save the embarrassment from the ungainly appearance.

When I first saw her the neck measured fourteen and a half inches in circumference. The faradic current was applied as strong as could be borne for fifteen minutes, placing the poles on opposite sides of the neck over the thyroid bodies.

At the second sitting the neck measured fifteen inches, an increase of half an inch. After this it began to rapidly diminish in size, and after ten sittings it had reached the normal size, measuring twelve and a half inches, and has remained so ever since (four months).

Respectfully, M. B. VEEDER, M.D.

CENTRAL SQUARE, N. Y.

SURGICAL INTERFERENCE IN TYPHOID FEVER.

To the Editor of THE MEDICAL NEWS,

SIR: In your interesting leader on "Surgical Interference in Perforated Typhoid Ulcer" (THE MEDICAL NEWS, November 26, 1892, p. 613), you observe that "But two text-books refer to the possibility of surgical interference in this form of perforative peritonitis."

If you will kindly refer to page 472 of my *Text-book of the Eruptive and Continued Fevers* (reviewed in THE MEDICAL NEWS, July 30, 1892), you will find the question, "Shall Laparotomy be Performed for Intestinal Perforation in Enteric Fever?" fully discussed and ample justice done to Dr. Weller Van Hook's paper (THE MEDICAL NEWS, November 21, 1891).

I remain, dear Sir,

Yours faithfully,

J. W. MOORE.

40 FITZWILLIAM SQUARE, WEST DUBLIN.

NEWS ITEMS.

Regulation of the Milk-supply.—At a recent meeting of the New Jersey State Sanitary Association, Professor Leeds made a most earnest and urgent appeal for a more stringent regulation of the milk-supply in the interest of the public health, and especially as far as infants are concerned. The immediate occasion of the appeal was the revelation of the deplorable and dangerous condition of the cattle in Hudson County, although similar conditions likewise exist in other parts of the State. After the swill-milk stables had been driven out of New York City and Brooklyn, their proprietors took refuge on the Jersey side of the Hudson river. Over two thousand stables, with upward of ten thousand cattle, are given up to the manufacture of brewers' grains into milk, the cow being the factory in which this nefarious business is carried on. In many cases the fresh cow is driven into a stall, her head is fastened to a board with a vertical slot, so as to admit of no motion except an up-and-down movement of the head. Thus imprisoned, the cow is fed exclusively on brewers' grains until she sickens or runs dry. The stables are filthy, unventilated, and shockingly foul. The feeding results in chronic diarrhea, and the cow is no longer capable of calving again, but is sold for butchers' meat.

The crowding, heat, filth, and lack of ventilation cause the animals to fall victims to disease, so that tuberculosis and other dangerous maladies run riot among them. The milk, even when the cows are not diseased, is not fit for food. It spoils rapidly, has an unpleasant odor, forms a hard, indigestible curd, and contains actively poisonous principles; but very commonly the cow is tuberculous or otherwise diseased, and then, in addition, the germs of disease are present in the milk, and, without their origin being suspected, illness and death are carried to multitudes of children.

The water used in these stables is frequently taken from wells in the yards, which are simply drains for manure and sewage. This water is used in washing the cans and utensils and in watering the milk. Such water is full of impurities and bacteria and powerfully assists in the dissemination of disease. Not only in these stables but throughout the State, tuberculosis among cattle is prevalent to a dangerous extent. The remedy for these evils is to be found in an efficient system of official dairy-inspection and sanitary milk-control. Only by this means can pure milk from healthy cows be delivered to the consumer in the same wholesome condition as when freshly drawn at the dairy. To this end tuberculous cattle should be killed. Moreover, the State inspectors should not only see that all persons engaged in the production and sale of milk are carrying on the business in conformity with the State laws, but should also be required to issue licenses to them for a limited period, say for one year, to that effect, such licenses to be forfeited on infraction of the law. The effect of these regulations would be to confine the milk-business to suitable country dairies, and to farmers and others competent to carry it on in a safe and proper manner.

Railway Accidents in the United States.—According to the Report of the Interstate Commerce Commission the following were the railroad casualties for the year ending June 30, 1891: The number killed during the year was 7029, and the number injured was 33,881. Of these totals, the number of employés killed was 2660, and the number injured was 26,140. The number of passengers killed was 293, and the number injured was 2972. A classification of casualties according to the kind of accident shows that 415 employés were killed, and 9431 injured while coupling and uncoupling cars; 598 were killed and 3191 injured by falling from trains and engines; 78 were killed and 412 were injured from overhead obstructions; 303 were killed and 1550 were injured in col-

lisions; 206 were killed and 919 were injured from derailment of trains; 57 were killed and 319 were injured from accidents to trains other than collisions and derailments already mentioned; 20 were killed and 50 injured at highway crossings; 127 were killed and 1427 were injured at stations; the balance, which makes up the total of 2660 killed and 26,140 injured, is due to accidents which do not naturally fall in the classification adopted for report. Referring to passengers, 59 were killed and 623 injured by collisions; 49 were killed and 837 injured by derailments; 2 were killed and 34 injured by other train-accidents; the balance, making up a total of 293 killed and 2972 injured, being assignable to accidents at highway crossings and at stations, and to other kinds of accidents.

Not only is the number of accidents of the year covered by this report greater than that of previous years, but, when compared with the increase in employés, it is observed that it is relatively greater than that of the previous year. Thus, during the year ending June 30, 1891, 1 employé was killed for every 296 employés, and 1 employé injured for every 30 men in railway service. The corresponding figures for the previous year are: 1 man killed for every 306 employés, and 1 man injured for every 33 employés.

Third Congress of American Physicians and Surgeons.—The first meeting of the Executive Committee of the Third Congress of American Physicians and Surgeons was held December 27th, in Philadelphia. The committee was organized by the election of Dr. William Pepper as chairman, and Dr. Newton M. Shaffer as secretary. The following officers of the Congress were elected: Dr. A. L. Loomis, of New York, president; Dr. W. H. Carmalt, of New Haven, secretary; Dr. John Shaw Billings, of Washington, treasurer; and Dr. S. C. Busey, of Washington, chairman of the committee of arrangements. It was decided to hold the next meeting in Washington in May, 1894.

The Clinical Journal is the name of a new publication emanating from London, of which some ten numbers have already appeared. Each number is promised to contain one or more lectures or articles, short clinical notes, prescriptions, and a series of articles on the spas and baths of the United Kingdom and Europe. From time to time a supplement will be issued, containing notes of recent books and other publications, clinical reports on drugs, foods, and instruments and other appliances and articles recognized and used for medical and surgical purposes.

The Medical Society of the State of Pennsylvania will meet at Williamsport, May 16th, 17th, 18th, and 19th. All who desire to read papers at the session must submit them, not later than March 1st, by title, to Dr. H. G. McCormick, Chairman of the Committee of Arrangements, Williamsport.

CORRECTIONS.—In THE NEWS of January 7th, the word *unwillingly*, line 3, page 27, first column, should have been printed *unwittingly*. On page 12, second column, second line from the bottom, for *vaginal* read *virginal*.

ORIGINAL ARTICLES.

A CONTRIBUTION TO THE SUBJECT OF ACUTE PLEURISY: ITS PATHOLOGY, ETIOLOGY, SYMPTOMATOLOGY, AND TREATMENT.[1]

BY FRANK S. PARSONS, M.D.,
OF NORTHAMPTON, MASS.;
FORMERLY LECTURER ON DISEASES OF CHILDREN IN THE COLLEGE OF PHYSICIANS AND SURGEONS, BOSTON, MASS.

THE proper classification of an inflammatory affection of a serous membrane, and especially of the pleura, is not an easy task. The terms "acute," "subacute," and "chronic," that have been applied to diseases of that nature, are often subjects of much criticism, no matter what pathologic lesions or symptomatic indications they may be derived from.

In considering acute pleurisy, I shall not hope to unravel these disputed questions, and only trust that I shall not fall into the common error of making them more intricate.

The term "acute" pleurisy indicates an inflammatory condition, more or less general in extent, of the serous membrane lining the pleural cavity, with sero-fibrinous or purulent deposits, primary or secondary in nature, of microbic or other origin, with a certain degree of sharpness of attack, and in which the height of the disease is attained in a few days, ten at the most, and accompanied by a rise in temperature of greater or less extent. Acute pleurisy may thus be (1) dependent on preëxisting disease or lesions, the development of which may cause sudden intense inflammatory conditions of the pleura, more or less extensive; or (2) it may be an idiopathic disease.

PATHOLOGY.—Hyperemia, or congestion of the bloodvessels within the serous and subserous connective tissue, causing swelling, redness, and edema of the pleura, is the first noticeable lesion of acute idiopathic pleurisy. This congestion may take place in some localized spot and rapidly extend to a greater or less degree; or it may, from the first, present quite a general appearance over the surface of the pleura. Soon the smaller and weaker capillary vessels rupture, producing ecchymotic spots over the membrane, and, at the same time, infiltration of the subserous connective tissue occurs, with a proliferation and detachment of epithelial cells. As the process progresses the pleura is studded with fine granulations upon its surface, in which appear embryonic cells. These tend to organize the newly-formed connective tissue into firm fibrinous bands, which, in old cases, are often found stretching across the pleural cavity, and constitute the so-called neo-membranes. Finally, from the congested serous membrane is poured into the cavity a liquid resembling in all respects the plasma of the blood, except that it is more dilute; the degree of dilution, however, varies with the intensity of the congestion, according to the coagulability of the fibrin in the effused fluid. There are, also, red blood-corpuscles and leukocytes in the liquid; but in simple sero-fibrinous pleurisy the red globules are not in sufficient numbers to cause any marked discoloration; if such occur, the pleurisy is termed "hemorrhagic."

"Inflammation," says M. Germain Sée,[1] "is a struggle for life, and not a destructive process; it is essentially a vital phenomenon eminently reactionary against a morbid agent." He believes that the teachings of microbiology show that inflammation is a physiologic process strongly exaggerated; a general struggle of the organism against microbic invaders. "The first step in this process," he says, "is leukocytosis, or the exaggerated production of white corpuscles in the blood; and the second is the absorption and destruction of microörganisms by these leukocytes, showing the defensive action of the latter; this is called "phagocytosis."

Certain physiologic functions are attributed to the phagocytes:

1. They carry from the albuminates in the intestinal canal material for combustion in the tissues.

2. Owing to their ameboid movements they are capable of transporting to distant parts of the body substances in their vicinity.

3. They possess, under certain conditions, a reproductive function, and a power of collecting themselves in vast quantities in certain localities.

4. They have what is known as a chemotactic function; so that the leukocytes thus play a considerable rôle in the morphologic contexture, as well as the chemistry of the body.

The French supporters of the germ-theory of disease believe that when microbes have penetrated the organism, the leukocytes increase; that the conditions that bring them to the blood carry them to the point of excitement, and that it is a chemical

[1] Read at the meeting of the New York State Medical Association, held in New York City, November 15, 16, 17, 1892.

[1] Bulletin de l'Académie de Médecine, May 10, 1892, p. 680.

property that draws them there. This, they claim, is true of all high-grade inflammations, as pneumonia, but not of the low grade, as malarial fevers.

In pneumonia there is an increase of leukocytes during the height of the disease, but as the fever abates the number of leukocytes diminishes. It is, therefore, held that the real termination of the disease, whether by crisis or lysis, occurs at the time when the leukocytes begin to diminish in the blood.

In acute inflammations there are three stages of development: First, vascular dilatation; second, activity and proliferation of endothelium; third, exudation, with diapedesis of leukocytes. As a consequence of these three stages it is claimed that a great afflux of phagocytes takes place toward the point of attack, both in purulent as well as in catarrhal inflammations; it is less seen in serous varieties, and, perhaps, not at all in infectious processes, the reason for this being that the infectious matters destroy the phagocytic function of the leukocytes, and hence the body has no protecting element against the enemy, and becomes the prey of the microbe. Suppuration is considered no exaggeration of inflammation, but is primarily due to the action of streptococci or staphylococci, and although great numbers of phagocytes may be found, yet their defensive action is much harassed by their deadly enemy, the pus-germs.

From the foregoing, if we are to accept this doctrine, we may conclude that inflammation is a physiologic process to develop phagocytes for the purpose of antagonizing microbes.

Anatomically the pleura is a great lymphatic sac, contiguous with the arterio-pulmonary system, and naturally derives its serosity from that source.

According to the eminent French teacher, M. Guerin,[1] "pleurisy is nothing else than lymphangitis." "If one injected the pulmonary artery," says Guerin, "with colored liquid, it would be found that the liquid would appear in the polygonal ramifications of the lymphatics of the pleura."

Moreover, he has practised on the cadaver the injection of bullock's blood in the same manner, and finds that he obtains a serosity from the pleura which, if much force is used in the process of injecting, becomes bloody, or red in color. This is on the healthy lung and pleura. If, on the other hand, he injects a colored liquid in a subject that has suffered and died from pleurisy, there will be found no coloring-matter in the meshes of the lymphatics except those that have not been affected by the inflammatory process. If this be true, we can readily see that when from some cause the lymphatics of the pleura become congested and swollen, and the natural channels for the lymph impeded, an edematous condition of the subserous connective tissue will arise, due to forced diapedesis of the serous exudate, and cause the fluid to ooze from all parts into the cavity.

If, then, the lymphatic stoppage is complete enough, and the force behind is strong enough, there will also be more or less diapedesis of red blood-corpuscles, and hence the hemorrhagic pleurisy. If we find leukocytes in the lymphatic exudation, does that not best explain the formation of pus? It has been stated that the serous exudate of acute pleurisy does not differ materially from the plasma of the blood. (The reason for this appears plain if we consider the contiguity of the arterial capillaries with the lymphatics.) If drawn off, it will coagulate, often spontaneously; if beaten or whipped, it will show a deposit of fibrin; and the constituents are the same as the plasma of the blood, except in relative proportion.

It often happens, when one is practising puncture to draw off the effusion of acute pleurisy, that the needle, if small, becomes clogged with fibrinous flocculi. From this fact, it is argued by M. Lancereaux,[1] that these flocculi, and more especially the finer ones, become obstructed in the openings of the lymphatics and produce a mechanical hindrance to the exit of the effused fluid by the thrombus thus formed. When this has occurred to such an extent that it impedes the absorption of liquid beyond the natural time required for the evolution of the disease, he avers, "one must wait for the disintegration and absorption of the clot before any diminishing of the quantity of the fluid by nature takes place."

Secondary pleurisies, or those acute attacks from some preëxisting disease which often occur, doubtless present in many cases the pathologic lesions in the pleura upon which such disease depends; but I can see no reason for the opinion of some authors, that every pleurisy is dependent on lesions of preexisting maladies, and especially tuberculosis.

ETIOLOGY.—In considering the causation of acute pleurisy, one must of necessity admit that there are two general classifications from an etiologic point of view:

a. Those that are not due to any preëxisting disease;

b. Those that are so due.

At the present day there are many and diverse opinions held by eminent medical men as to the factors that produce primary idiopathic pleurisy. There are, indeed, those who would go so far as to say that all pleurisies are tuberculous in origin, and, hence, secondary.

[1] Bulletin de l'Académie de Médecine, April 26, 1892.

[1] Bulletin de l'Acad. de Méd., May 3, 1892, p. 661 *et seq.*

Undoubtedly, many pleurisies deemed primary are in reality dependent on some complicating or preëxisting disease; but to say that a person must be weakened by constitutional maladies in order to become privileged to have pleurisy, seems as if we were carrying the causative factors beyond the point warranted by our pathologic research. I doubt not, if the chests of many persons who to-day are in good health and have never been cognizant of pleurisy were opened, we would find various traces of old adhesions and other ancient lesions of former pleurisies.

It must, therefore, be admitted, even at the present day of biologic research, that the etiology of acute pleurisy is often obscure: the microbe will not account for all the cases; neither will any other one causative factor. While it is difficult to state with certainty that pleurisy originates in perfectly healthy persons, because latent pathologic lesions cannot be appreciated, yet we know that it does occur in persons who to all appearances, to themselves and others, are in good health. M. Sée[1] maintains that the etiology of acute pleurisy is always microbic; in fact, that it is a bacterial disease; cold is simply a stimulus to the activity and development of the microörganisms.

M. Jaccoud[2] is of the opinion that in the human body many kinds and many thousands of microorganisms live in peace and harmony together so long as the functions are normal, but let a disturbing element arise, such as taking cold, and their physiologic relations become altered, so that they soon are hostile to each other and cause disease. Netter[3] claims that all forms of pleurisy are of microbic origin, but that the microbes producing them are of many different kinds.

M. Bechamp[4] says: "Microbes do not have so much importance in acute pleurisy as some would have them." He is certain that pleurisy may exist independently of tuberculosis, from the fact that at the age of thirty he was seized with acute pleurisy, and after the usual bleeding, blistering, and purging, he now, at the age of seventy-six, is still alive, and has not developed tuberculosis. In support of this, both he and Dieulafoy state that, in many cases, persons live ten, fifteen, and more years after the operation of thoracentesis, and do not develop tuberculosis.

That exposure to cold has a tendency to excite inflammations, and with them acute pleurisy, is no doubt true. Whether its influence is exerted through the nerve-centers, so as to directly cause pleurisy, or whether it acts simply as a stimulus to organized germs through whose activity the disease originates, is still a much-mooted question. M. Tresbot[1] does not doubt that acute pleurisy in horses is the direct result of an exposure to cold, especially when, after a long, hard drive the animal is allowed to stand unprotected and exposed to a chilling wind. He says that "ordinarily there is nothing in common between sero-fibrinous pleurisy in the horse and tuberculosis;" and also that "it is impossible to class sero-fibrinous pleurisy in the horse with an eruptive fever, or, indeed, with any periodic disease." On the other hand, M. Lancereaux[2] asserts: "Pleurisy should be rightly classed among the infectious maladies, and exposure to cold is nothing but an occasional exciting cause, while the action of the infecting agent still escapes us."

If we should accept the pathologic views of M. Guerin,[3] we might easily explain the causation of the congestion of the bloodvessels by peripheral irritation, and reflex action of the vasomotor nerves from exposure to cold. This, however, does not explain why such excitement should be directed particularly to the pleura.

In a paper on "The Cause of Syncope in Pleurisy," M. La Borde[4] has illustrated by experiment on animals that it is possible to produce a sero-fibrinous pleurisy in a few hours by the action of cantharidin injected into the blood. This leads me to ask the question, Is the causation of acute primary pleurisy ever, in a measure, governed by the ingestion of certain articles of food, taken just previously to an exposure to cold, *i. e.*, is the combination of the two forces sufficient to direct the action of inflammation toward the pleura?

The cause of acute purulent pleurisy is probably of microbic nature. Purulent pleurisies either begin as such, or are secondary to other diseases. Age and debility have much to do with the formation of pus, the young and aged being more susceptible to empyema. It is doubtful if simple sero-fibrinous pleurisies are ever transformed into the purulent form without the aid of outside interference.

Secondary pleurisies occur from a variety of causes, mostly from diseases microbic in origin.

While it may be rare to have pneumonia occur without some localized extension of inflammation to the pleura, it is doubtful if a general acute pleurisy, secondary to pneumonia, can be found without numerous pneumonia-cocci. In the same manner, the causation of pleurisy during an attack of typhoid fever, influenza, malarial fever, rheumatism, and kindred diseases, is undoubtedly due to the same influences that govern the coëxisting disease.

[2] Ibid., May 3, 1892.
[3] Loc. cit.
[4] Bulletin de l'Académie de Médecine, May 17, 1892, p. 709.

It is well known that pleurisy of an acute type may be secondary to tuberculosis; but there is considerable difference of opinion as to the proportion of cases arising from this source. M. Sée[1] claims that 68 per cent. of all pleurisies are due to this cause. This seems high, or else persons radically recover from tuberculous pleurisy more often than from any other form of tuberculosis. Dr. G. G. Sears[2] reports four hundred and fifty cases of pleurisy, of which 39 per cent. developed tuberculous disease. Others state that not more than 20 per cent. of pleurisies are tuberculous in origin. The differences, probably, lie in the particular train of cases various observers have met.

There is, however, no doubt that a certain number of cases of tuberculosis have their initial symptom manifested by an attack of acute pleurisy.

Symptomatology.—M. Lancereaux and other French observers believe acute pleurisy to be a well-defined cyclic malady,[3] because its lesions are always found unchangeable, and its evolution is as constant as that of pneumonia or of typhoid fever. It presents regular pathologic changes after each seventh day, and this fact allows a classification of the disease into three periods of evolution.

First: Seven days represent the time occupied for the increase of the pathologic lesions, at the end of which the effusion reaches the limit of its advance.

Second: The next seven days represent the time during which the pathologic lesions appear to remain stationary, and the effusion has not undergone any perceptible alteration in amount.

Third: From the fifteenth to the twenty-first day of the disease there takes place an absorption of the inflammatory products, including the effusion. These divisions, of course, cannot be made absolute, because individual cases differ among themselves; thus we all know that fluid-accumulations often completely fill the pleural cavity before the expiration of the first seven days, and when withdrawn reaccumulate; however, we may confidently expect at the end of the first period that in uncomplicated cases there will be no further effusion of fluid.

Each of these three stages has its respective symptoms, but they pass from one to the other without any pronounced expression of change.

In a majority of cases the first period of acute pleurisy is ushered in with a chill, announcing a greater or less rise of temperature, and accompanied with more or less pain in the affected side.

The pyrexia will generally determine the intensity of the inflammation; it seldom rises above 102° or 103°, unless the pleurisy is secondary to some other disease. Pain, which appears with the pyrexia, may begin as soreness in a circumscribed spot and progressively increase to an unbearable intensity; or it may at first be sharp and lancinating, at or below the nipple, from which point it becomes more or less diffused. The pain is increased on motion, and, for this reason, respiratory efforts are, so far as possible, restrained. A dry, hacking cough is generally present, but the pain it occasions calls for efforts at its suppression. After a few hours, when the effusion appears, the pain is moderated and gradually disappears, or its intensity is greatly diminished. The pulse is increased in frequency and generally firm, the rate varying between 100 and 120. As the disease progresses, dyspnea is often developed, and this may be due to several different causes. It may indicate abundant effusion, and be due to compression of the lung or displacement of the heart; it is most commonly a result of one of these. Again, it may be due to congestion of the lungs independently of compression. Edema of the lungs, capillary bronchitis, and rheumatic difficulties sometimes occasion dypsnea when very little fluid can be found in the cavity. Encysted pleurisies occasionally cause pain and dypsnea. Irregularity of the pulse and cyanosis are grave symptoms, largely dependent on displacement or weakness of the heart. Syncope may also be occasioned in various ways; the reflex action of pain is one of its chief causes, as we may often produce it artificially by electrifying some peripheral sensory nerve. Again, when the fluid fills the pleural cavity and is suddenly drawn entirely away, the reaction that follows may cause syncope.

Physical Signs.—These vary with the quantity rather than quality of the effusion. In the early stages of the disease they often establish the diagnosis, and in the later stages they determine the amount of liquid in the cavity of the chest. On inspection there is in the early stages restricted motion of the affected side, dependent at first on the amount of pain, and later on the accumulated fluid. The comparison with the sound side is very striking. In left-sided effusions there may be displacement of the heart-beat to the right of the normal, and when large effusions occur on the right side, displacement is sometimes to the left. On palpation, vocal fremitus is lost over a collection of fluid, and if the effusion is large on the right side, the liver may be felt to be displaced. On percussion, we may early find dulness over the lower posterior portions of the chest; this dulness gives place to flatness as the effusion appears and advances; above the fluid the percussion-note remains dull, while at its level, and below, it becomes flat. It will be remembered that the level of the fluid is not a hydrostatic one; but from the elasticity of the lung the level assumes a shape

[1] Bulletin de l'Académie de Médecine, April 19, 1892.
[2] Boston Medical and Surgical Journal, Feb. 25, 1892.
[3] Bulletin de l'Académie de Médecine, May 3, 1892.

resembling the letter S. Over the sound lung the vesicular resonance is more or less exaggerated. Dulness is likely to remain for a considerable time after the effusion has been absorbed. On auscultation, the respiratory murmur is enfeebled or absent, for the same reasons and in the same progressive manner as the loss of resonance on percussion occurs. Friction-sounds are sometimes heard at the beginning of the disease, but are more common at the close of the third stage. Some observers have indicated that the transmission of the whispered voice, or its absence, has direct relation to the diagnosis of serous or purulent effusions, but this is doubted by others.

No lengthy discussion of the physical signs of acute pleurisy is necessary here; these do not differ from their description as set forth in our modern text-books.

TREATMENT.—In considering the treatment of acute pleurisy we must recall the classification of its etiology, viz.:

First: Those cases that are dependent on some other disease for their cause, whether influenced by microbes or not, and hence are secondary pleurisies.

Second: Those cases that are of spontaneous origin, considered idiopathic, and hence are called primary pleurisies.

Physicians may likewise be divided into classes: those who consider pleurisy to be always a microbic disease, and those who do not.

In a recent discussion on this subject the eminent French author, Hardy,[1] said that acute pleurisy of sero-fibrinous nature was no better treated to-day than it was fifty years ago, and, except in purulent forms, no better results were obtained now than then, the death-rate at present being 10 per cent., the same as in the days of our forefathers. This statement may be astonishing to some of us who have been taught to look upon acute pleurisy as a not very fatal disease; however, some statistics would seem to bear out this opinion. Perhaps it would, therefore, be well to consider the modern methods of treatment and then compare them with those practised in the early part of the century.

To undertake the consideration of all the medications for pleurisy that have been launched upon us during the past few years would take more time and space than would be profitable for me to employ; suffice it to say that a majority of them have passed into disuse.

The modern medical treatment of acute pleurisy is by the following class of agents: First, by antiseptics, to combat microörganisms; second, by antipyretics, to combat fever; third, by evacuants, to eliminate the fluid.

[1] Bulletin de l'Académie de Médecine, May 1, 1892, p. 776.

Dr. Charles Talamon[1] has recently called attention to the action of sodium salicylate in pleuritic effusions, claiming for it the power of promoting rapid absorption of the fluid. He thinks it has a direct action on the inflamed pleura, because by the experiments of Rosenbach it is proved that the salicylates may be found in the serous cavities of the body after their ingestion by the mouth in doses of from ten to twenty grains. Whether the beneficial action on the fluid is due to the antiseptic nature of the agent, he does not state, and whether it is due to this or its diuretic action is still an open question. That sodium salicylate may be of use when the pleurisy is secondary to rheumatism there can be no doubt, but in the primary form to depend on its success as a germicide would be hazardous. However, the salicylates may be employed as antipyretics as advantageously as other remedies; they certainly combine the indications for an antiseptic, antipyretic, and diuretic.

The practice of injecting a solution of salicylic acid or other antiseptic into the pleural cavity to combat microbes in the effusion has been suggested by some, but the treatment seems harsh and uncalled for, unless employed in connection with surgical methods for the treatment of empyemas.

Antipyretics in acute pleurisy are only indicated when the fever rises to 101° or over, and as the fever seldom attains that height for any length of time their use is greatly modified.

Quinine may be advantageously employed in pleurisy depending on malarial poisoning, and during convalescence, as a tonic. Antipyrin, or the other coal-tar derivatives, may be useful in cases accompanied by hyperpyrexia, but none of these measures is calculated to reach the cause of the disease, or to modify its pathology.

The evacuants are administered in acute pleurisy with a view to reduce the amount of effusion after its accumulation.

Under this head, the diuretics play the most important part. Digitalis may support a weak heart, but its action in reducing a pleuritic effusion is small. Milk is often used as a diuretic, but its influence over fluid in this disease is doubtful; while as a food it ought not to be neglected.

The action of purgatives, drastic or saline, and of sudorifics, with a view to reduce the quantity of liquid in the chest, is of no value; moreover, they are often dangerous.

The pleuritic effusion is not really a question of hydropsy; the liquid of general ascites furnishes a chemical analysis quite different from the effusion of pleurisy; the latter is not simply a serum from the blood, but blood-plasma.

[1] New York Medical Journal, January 2, 1892.

In a recent paper on "The Treatment of Pleuritic Effusion," M. Sée[1] draws the following conclusions: "Antiseptics, diuretics, sudorifics, and purgatives, drastic or saline, have no kind of action on the effusion. Milk, which is a powerful diuretic, has no value here, except as a food. No one of these microbic diseases derives the least benefit from venesection. All aggravate the onset of the disease. Expectation is the only rational method of treatment, for sero-fibrinous pleurisy regularly passes through its different phases in two or three weeks, and up to that point all medication is useless." In a recent paper on this subject, M. Lancereaux[2] says: "There is no more use in trying to ward off pleuritic fever than to ward off pneumonia or typhoid fever; however, it is necessary, relying on our pathologic knowledge of the lesions of acute pleurisy, to draw attention to the coagulation in the lymphatic system, and strive to remove it; while we may not succeed, it is the best practice to try."

In discussing the subject, M. Guerin[3] says: "This idea of pleurisy being a simple lymphangitis also gives a clear explanation of the sudden reabsorption of fluid in some cases that for a long time have proved refractory to all treatment. It indicates that the coagulum in the absorbent vessels has become reabsorbed and makes it possible for the fluid to be taken up; we should therefore attempt the prompt moderation of the lymphangitis."

Of late, in the excitement of bacteriologic investigations, the profession had been content to disregard the teachings of our ancestors, and the good old methods in vogue at their time. We have regarded these diseases as cyclic in nature; maladies that must run their regular course in spite of all abortive treatment; sicknesses that are caused by microorganisms over which we have no control; hence, we must fold our hands and content ourselves with relieving of pain, until such time as the particular germ has loosened his besieging grasp.

This is the "expectant treatment of to-day, and this is the treatment eminent authorities hold out to us for acute pleurisy." "The expectant treatment," says Peter,[4] "is the do-nothing treatment, and this is what many bacteriologists practise. No physician has a right to practise inactivity in these cases when so much can be done toward curing pleurisy if energetic treatment is begun early."

To allow a patient to become weakened by pain and suffering, because pleurisy is a cyclic disease and should terminate spontaneously in two or three weeks, or, because the pathologic conditions are such that, by deferring active measures, one may with impunity puncture the chest and draw off a liter of fluid, is treating the wrong end of the disease. A physician should strive to diminish the intensity of a malady, if, indeed, he cannot shorten its duration.

What are the indications for treatment in acute pleurisy?

Briefly, they are as follows: 1. The relief of pain. 2. The reduction of fever. 3. The arrest of effusion. All of which depends on treating the cause.

It was of these indications our ancestors had a rare knowledge when they applied bleeding and localized vesications; when practised, these at once relieved the pain, reduced the fever, and there was little or no serous effusion found in their cases; moreover, if in this they were not entirely successful, the harshness of the sickness was notably diminished. By these methods the pathologic lesions were affected, and the cause of the pain and fever reached. In 1819, Laennec said: "If a plethoric subject had pleurisy, he required bleeding."

While it is undoubtedly true that the pendulum of exsanguination in inflammatory diseases oscillated too far in the early part of this century, and to the detriment of many, is it not also true that at the present time it has swung too far the other way, and "expectant treatment" is employed to the detriment of many? I believe the antiphlogistic treatment is indicated in just as many cases of acute pleurisy now, as in the days of our forefathers. That the treatment may be carried too far I do not deny; the judicious use of it at the right time is the essential point. Pain is almost wholly relieved by the revulsive methods in a short time; this probably being accomplished by the removal of the congestion and its baneful influences, if revulsion is practised early. At the present time, and in some form, opium is employed for the relief of pain; but does it lessen the congestion causing the pain, or simply dull the sensibility to the pain which is the result of the congestion? Revulsion lowers the fever, for which we now employ antipyretics, but will the antipyretic drugs alter the pathologic condition within the pleural cavity?

Farther on in this disease we often employ puncture of the chest to draw off the fluid, but have we not allowed the malady to reach that point by an early neglect to treat the cause efficiently, and thus converted what should have been a medical case into a surgical one? This certainly is to be deplored. Peter[1] goes so far as to say, that "By revulsive methods, early employed, one is able to prevent the serous effusion in many cases; to arrest it, if the secretion has begun to form, and finally to absorb it, if a small amount has collected." Andral and Bouilland[2] cite thirty cases in one year, treated anti-

phlogistically, with one death—percentage of mortality of three. Of seventy cases reported[1] in 1891, treated after the modern methods, there were seven deaths—a death-rate of 10 per cent. from acute pleurisy.

How should revulsion be employed in these cases?

Bouilland used to bleed twice and afterward apply wet cups and a large blister. This seems too energetic; yet I have recently been told by an elderly physician of my neighborhood that he once bled a woman with puerperal peritonitis until she fainted, and she had no more symptoms of the disease, and was soon about. One might employ wet cups and vesication more mildly, with equal success. "What is remarkable in these cases," says Peter,[2] "is the toleration of the system to these large bleedings, the rapidity with which the pain ceases and the local symptoms of pleurisy diminish." On the other hand, "Bleeding," says Sée,[3] "after doing so much harm, is springing up again insidiously in many diseases; it has no theoretic basis, and is little better than empiricism."

Can we learn anything from Nature as to the treatment of acute pleurisy?

There is pain from irritation of the intercostal nerves, due to the evolution of pathologic processes. Nature, in consequence of this inflammatory action, evolves a fluid which acts as a sedative to the injured nerves, and, little by little, the pain subsides. The fluid comes from the blood. This fluid is found to be exactly like the plasma of the blood, except in proportion; is it, therefore, not natural to assume that Nature bleeds her patient in the early stage of pleurisy? To be sure it may be the result of a congested condition, and, hence, one of pathology rather than one of treatment; nevertheless it depletes the vascular system, which, if we anticipate Nature by doing ourselves, we thereby arrest the pathologic condition and relieve Nature.

Regarding the application of blisters, there is a diversity of opinion, although it is generally held that they are useful adjuvants to scarification.

Metschnikoff advances the idea[4] that cantharides possesses an anti-bacterial tendency, and produces leukocytes which act as phagocytes, and proceed to destroy or change the character of the microbe. He would, therefore, inject a solution of cantharidin subcutaneously. Tresbot[5] has no doubt that a cantharides blister is of great value in the treatment of the pleurisy of horses. La Borde,[6] while advocating the use of cantharides blisters, calls attention to the fact that this agent is a poison, and capable of producing inflammation of the lung, bladder, or other viscus, and cautions against its use. There has been some belief that cantharides predisposes to the transforming of serous effusions into purulent ones, and especially in tuberculous patients. Potain denies this,[1] or the possibility of its happening, and maintains that a purulent effusion always starts as such. Counter-irritation may also be effected by the tincture of iodine painted on the surface of the affected side. Little in addition can be said of the treatment of purulent pleurisies prior to surgical interference, which is almost always required.

There is no positive way to differentiate them from the serous varieties, except by explorative puncture, but the indiscriminate use of the exploring-needle, ten or a dozen times, as recommended by some,[2] in search for pus, is to be condemned, even if no harm should chance to arise.

It is in childhood and old age that purulent pleurisy is most likely to occur. Why this is so, unless from a weaker state than is present in adults, is not easily determined; but in the treatment of this affection in children, this fact is to be borne in mind.

THORACENTESIS.—This operation, though always to be deplored, is often urgent and often useful. A discussion of its history, which may be found at length in *Pepper's System of Medicine*, is unnecessary in this place. Of late there has been much criticism for and against the operation by eminent authorities. That aspiration, as first practised by Bowditch, and later elaborated by Dieulafoy and others, is a simple, harmless operation, there can be no doubt; results will bear this statement out. All that is essential to the safety of the operation is thoroughly aseptic instruments, especially the aspirating-needle, and also some little skill in manipulation.

Thoracentesis, as practised by the majority of general practitioners, with any kind of trocar, which may have been used by them to open some abscess-cavity, or even with an aspirating apparatus that has not been perfectly cleansed, is a very dangerous operation.

It has been held by some that after the operation has been performed two or three times it produces a transformation of a sero-fibrinous effusion into a purulent one. This may be so; I do not deny that it often happens, but it is the operator and his unclean instruments that are at fault, rather than the effect of a puncture of the pleura; this is the reason we see one operator successful where another meets with failures.

As a rule, aspiration should not be performed in simple sero-fibrinous pleurisy until after the third week of the disease; and then only as the fluid tends

to remain stationary and unabsorbed, unless there is urgent need of interference to save life before that time. If the cause of the non-absorption of the fluid is (according to the views of Lancereaux) a stoppage of the lymphatics of the pleura by the formation of fibrinous thrombi in their orifices, and if we must wait until a disintegration of the clot takes place before the fluid will be absorbed, then no amount of aspiration will hasten the process of natural absorption until that time has expired. Moreover, the drawing off of the fluid will in many cases only tend to its reaccumulation up to the point it previously reached, because, according to his theory, if the fluid remains stationary to a given level or height within the cavity of the chest, there must be stoppage of all the lymph-spaces below that level; hence, no absorption is possible. If, then, we remove a part or the whole of the fluid, we do not necessarily remove the stoppage, and the reaccumulating fluid will in time reach its former height.

On the other hand, if, before practising thoracentesis, we wait until the disease has reached that period when we may expect these clots to be disintegrating and being taken up by the system, we then may be of some service to Nature in hastening absorption. This period is at about the end of the twenty-first day of the disease. However, there are times previous to this period, when life is threatened by the accumulation of fluid in the pleural cavity to such an extent that it compresses vital organs. When this occurs, it becomes necessary to draw off a certain amount of fluid by asp ration, in order to relieve distressing symptoms.

By what symptoms can we know that this danger is imminent?

When the fluid-accumulation has progressed to the extreme degree, there is dyspnea, from compression of the lung; more or less cyanosis, if the heart be displaced; flatness on percussion over most of the affected side, and sometimes accompanied with bulging of the intercostal spaces. However, if we wait for these symptoms to appear, there are strong dangers of being too late to render the assistance necessary.

There is in these cases no infallible sign by which we may discover the best time to operate.

Dyspnea, as we know, may be due to other causes than compression of the lung or displacement of the heart, and consequent twisting of the large arteries by fluid. Cyanosis and syncope are signs that may arise from hearts weakened by excess of pain, with little mechanical interference from an effusion into the pleura.

The most reliable test is by percussion; as by it we may arrive at an approximate estimate of the quantity of fluid contained in the pleural cavity. When the line of flatness has reached the second rib on either side of the chest, the left or right, Dieulafoy estimates the quantity to be about 2000 grams, and states it is time to operate. If, with this percussion-sign, there is dyspnea and some cyanosis, it is time to hasten the operation; as, while it is not right to puncture the chest too early, it is also hazardous to postpone the operation too long.

If, as often happens after early operative interference, the fluid should reaccumulate more or less rapidly, and the symptoms of distress reappear, a second operation would be imperative, and probably later on others would necessarily follow.

Only so much of the fluid should be removed in these cases as will render the patient more comfortable from the distressing symptoms, or remove any danger of immediate collapse. Sudden death has followed the removal of the entire amount of effusion at once, death being due to the congestion occurring from the sudden return of the compressed and distorted viscus to its normal position. A symptom of this danger is said to be the albuminous expectoration observed in these cases. The fluid should therefore be withdrawn gradually through a fine needle, and not more than a third, or perhaps a half, of the total quantity of fluid in the chest-cavity be removed at once. It is better to perform the operation several times in this manner than to have a fatal issue from the evacuation of too great a quantity of liquid at once.

In purulent pleurisies no time should be lost in evacuating the pus, observing the same precautions necessary, if by aspiration, as in serous effusions. In children with purulent pleurisies, repeated aspirations are advisable before resorting to more severe surgical methods; but in adults, if a reaccumulation of pus occurs after one aspiration, it is usually better practice to treat the empyema as one would an abscess-cavity and establish a system of free drainage. As these several methods of drainage come strictly under the head of chronic pleurisy, I shall not occupy more time here with a discussion of them.

Finally, I wish here to suggest a method of treatment for pleuritic effusions that I must frankly state is at present a simple theory, because I have not had the time or opportunity to clinically test its value. It is the employment of electrolysis to cause absorption of pleuritic effusions, based on the same theories as when it is used in serous effusions elsewhere. In a word, the operation might be called "electrocentesis." I have not found that any literature on the subject has ever been published—or ever ought to be published; however, electrolysis, as we know, has been employed quite commonly in serous effusions of other localities, such as cysts, hydrocele, tumors, etc., with great benefit in many instances. Why should it not be used with benefit in the serous effusion of pleurisy?

Electricity is used to hasten the absorption of fluid in cysts; first, by its power to chemically transform the watery into gaseous elements; second, by its direct stimulating influence on the lining membrane of the sac.

Is there any reason to expect any different results from the use of electricity, in a similar manner, in pleuritic effusions?

The technique of the operation recommended includes the use of the electro-puncture needle, thrust into the effusion; a clay electrode attached to the negative pole of a galvanic battery, and placed on the outside of the chest-wall. A current of a strength of from 30 to 50 milliampères, and perhaps more, could be safely passed through the fluid in this manner. Care should be taken that the needle be not thrust farther than just into the fluid, so that we get only electric action on the effusion and the costal pleura, otherwise we might electrify some vital organ in a manner not pleasing. From this application of electrolysis we might reasonably expect more or less coagulation of fibrinous matter and absorption of the fluid portions of the effusion. This we might expect to be in proportion to the strength of the current, and the length of time occupied in allowing the current to pass through.

The class of cases this method of treatment would probably benefit would be those in which thoracentesis for any reason could not safely be performed; those in which there has been repeated reaccumulation of fluid after aspiration, especially those of chronic tendencies; and, finally, those of secondary nature, particularly the tuberculous.

All antiseptic precautions usually necessary in any such operation should, of course, be observed.

ANTISEPTIC CATAPHORESIS IN THE TREATMENT OF DISEASES OF THE UTERUS AND ITS APPENDAGES.

BY WALLACE A. BRIGGS, M.D.,
OF SACRAMENTO, CAL.

"MEDDLESOME gynecology" and "uterine tinkering" are getting to be set phrases with those who seek to envisage gynecology as a branch of operative surgery. Emerson I believe it was who said, in substance, that one truth cannot be stated strongly without doing injustice to some other truth. But the surgical exclusivists are not content with stating their truth strongly; they stoutly maintain that there is no other truth. The blind spot that Holmes says is normal to all of our brains no longer remains with them a spot merely, but invades whole convolutions, if not the entire anterior lobe of the cerebrum. For them the "sensitiveness" of the uterus exists as a reality instead of a myth, like "sensitiveness" of the peritoneum, dissipated by cleanliness and antisepsis. By their "damnable iteration" many of us have come to believe that the knife constitutes our entire gynecologic armamentarium. In consequence, abdominal surgeons, like the men of Roderic Dhu, spring from every cover, fully equipped to do the liveliest execution. I protest against this opinion and this practice. I deny that it is the *summum bonum* of woman to be relieved of the intrinsic insignia of her sex. We are indeed too often reduced to the sad and humiliating necessity of such mutilation, and so are we to that of amputations of legs and arms; but the world believes that amputations are to be averted rather than courted, and so it will soon believe of celiotomies. It is no less the duty of the physician to obviate the necessity of sacrificial operations than to perform them when indicated.

Rational methods of treatment, then, that propose a *restitutio ad integrum* of diseased organs and a coincident prophylaxis of disease by extension to important adnexa may not be contemptuously dismissed as "uterine tinkering." Such a method is the antiseptic treatment of endometritis.

In the report of the Committee on Gynecology of the Medical Society of the State of California for the current year, of which an abstract appeared in the May number of the *Occidental Medical Times*, I described this method somewhat in detail, and it is my purpose here to invite attention to one element only of that method, viz.: antiseptic cataphoresis.

It need not be assumed, for it has been demonstrated by the history of gynecology, the record of therapeutic groping and wandering in a pathologic dark continent, that the uterus is tolerant of everything but infection. Against infection in the treatment of diseases of the uterus and its appendages antiseptic cataphoresis appears the most positive and efficient safeguard.

As quoted by Thomas, Scanzoni says that he does not remember to have been able to cure a single case of abundant uterine leukorrhea of several years' standing. In the treatment of these cases, who has not exhausted every resource of the healing art, as well as the forbearance of his patients, who have at last departed for "fresh fields and pastures new," uncured and ungrateful?

How shall we explain the inveteracy of these cases? The investigations of Bumm have shown that the gonococcus is endowed with an "eminent invasive force." It penetrates both the epithelial and sub-epithelial tissues. In the case of a moribund paralytic, Bockhart has demonstrated that it invades the lymph-vessels and even the capillary bloodvessels, and, although his conclusions have been warmly controverted, I am inclined to accept them, not only because of their intrinsic probability (for we should expect less resistance from the tissues

of a paralytic inoculated at death's door than from the tissues of those who acquire gonorrhea in the usual way), but also because they afford a rational explanation of the occasional development of so-called gonorrheal rheumatism. In cases of metritis Peraire found in the mucous tissues and in the tissue-cells the same microörganisms as in the uterine secretions.

We need seek no further, I think, for an explanation of the monotonous futility of the applicator and the comparative efficiency of the curette. The chronically inflamed uterus may be not inaptly likened to a chronic abscess communicating externally by a long and tortuous sinus. To effect a cure, the mucosa of the former, like the walls of the latter, must be either disinfected or destroyed. Without in the least disparaging the curette, it may be said that the true spirit of medicine would incline us *ceteris paribus* to conservative rather than sacrificial procedures; to disinfection rather than destruction.

In the uterine cavity the applicator is a useless and dangerous instrument. While it does not disinfect either the walls or the cavity, it does produce abrasions that may be the point of departure of new and serious trouble. If thoroughly done, antiseptic cataphoresis obviates this danger absolutely. It disinfects not only the cavity, but also the mucosa of the uterus and produces important interpolar effects on the uterine and pelvic circulation and nutrition that are daily demonstrated clinically and yet are pronounced a figment of the imagination by those who, in electro-therapeutics, prefer intuition to experience.

Before proceeding to the consideration of the various conditions in which antiseptic cataphoresis is indicated, it may be well to describe the technique of the procedure itself. I have used several antiseptic solutions or electrolytes of which iodine in varying ratio, either in combination or in solution, is an essential constituent.

They are all efficient, but having observed two cases of severe frontal headache following the use of the stronger solutions of iodine, I have latterly used the weaker ones more frequently, although not exclusively. Either of the following solutions will be found satisfactory: beechwood creasote or camphor-creasote, 10; iodine, from 1 to 2; beechwood creasote or camphor-creasote, 10; sodium iodide, 0.5; iodine, from 1 to 2.

The patient is put in the semi-prone position, which facilitates the introduction of the electrode and the escape of gases developed by electrolysis. A self-retaining speculum is introduced, the vagina and cervical canal are cleansed, and the direction and size of the latter ascertained. If the canal of the cervix be not large enough to permit the ready passage of the electrode and the simultaneous reflux of uterine secretions, redundant electrolyte and electrolytic gases, it should be sufficiently dilated either with Hegar's bougies or with a pair of strong dressing-forceps.

The active surface of the combined intra-uterine syringe, applicator, and electrode is then wrapped with a thin layer of absorbent cotton, into which a small but strong thread is wound and left loose about the shaft of the instrument, for the purpose of withdrawing the cotton should it slip from the electrode and remain in the uterus. The anterior lip of the cervix is then seized and fixed with a small tenaculum, the electrode dipped in the antiseptic electrolyte, passed through the cervix, gently turned either to right or left, and carried well into one cornu. The conductor is now attached, and the current is turned on and slowly carried to the maximum desired. The electrode is allowed to remain in the cornu from one to three minutes, while from three to six or eight minutes are occupied in sweeping it across the fundus to the opposite cornu, where it remains again from one to three minutes, when the current is turned off and the electrode removed. During the passage of the current the electrolyte is injected, drop by drop, until from 5 to 10 minims have been introduced.

The applications of antiseptic cataphoresis in gynecology are numerous, and I shall now briefly consider those that I have found preferable to the treatment usually employed.

Chronic metritis, chronic endometritis, subinvolution, cervical endometritis, and cervical erosions are classed together because of the similarity of their origin, pathology, and treatment. It is probable that metritis and endometritis rarely exist as separate and distinct diseases, but that each ordinarily accompanies the other, and when predominating gives name and characteristics to the dual affection. Endometritis would seem to be the primary disease which by extension produces and by persistence maintains an inflammation of the uterine parenchyma. Subinvolution is the product of uterine infection engrafted on the puerperal condition. All of the affections here grouped together are of infectious origin, and in all of them the uterine cavity and the mucosa are the breeding-ground of the infectious organisms. Cure is to be effected by the removal, first, of the cause of the disease, and secondly, of the results. Disinfection, then, complete and permanent, constitutes the causal treatment. For this purpose, nothing in my experience compares with antiseptic cataphoresis, which may be used when perhaps any other form of local interference might not unjustly be termed "meddlesome," as the history of the following cases will indicate:

Mrs. S. came to my office April 23, 1892, complaining of profuse leukorrhea, of pain in the pelvis and back, and of supra-pubic tenderness. She was unable to be on her feet for any length of time, and had given up her position of housekeeper, because unable longer to perform its duties, and had spontaneously taken to bed, where she had remained most of the time for the previous week. Rest had given her little relief, and she was barely able to get to my office—just a square from her room.

The uterus was found swollen, tender, retroverted, and discharging a large quantity of muco-purulent secretion. A circular erosion of the cervix, about an inch in diameter, surrounded the os. The adnexa were tender, although no evidence of purulent accumulation could be discovered.

Positive antiseptic cataphoresis was practised every third day, and antiseptic packing every day from this date until May 24, 1892. Constant and rapid improvement was manifest from the first application, and on June 1st, while there was still a slight mucous discharge from the cervix, the subjective symptoms had disappeared entirely, and the patient went to work in a hotel, where she made sixty beds daily, besides doing much other chamber-work. She has reported twice since, looks and feels well, and continues at her work.

Mrs. P., housekeeper, sent for me May 10, 1892. She had been suffering for three or four months with profuse leukorrhea, menorrhagia, pain in the pelvis and sacral region radiating down the thighs, becoming so severe at the menstrual periods or on exertion as to keep her in bed. The uterus was sensitive, swollen, and retroverted. A profuse muco-purulent discharge was issuing from the cervix. The peri-uterine tissues were so tender as to give rise to the suspicion of perimetritis. Under phenacetin and bromide, however, the pain subsided and the patient was able to ride to the office on May 16th. The uterus was tender and the discharge unabated. Positive antiseptic cataphoresis (40 m.a. 10 minutes) was employed and repeated every third day until June 15th. Immediate and rapid improvement was manifest, and on June 25th the metritis had wholly subsided, and the patient, although retaining the displacement, considered herself well, and was discharged.

SALPINGITIS.—Schroeder believes that salpingitis is always secondary to endometritis, and that the mucosa furnishes the only pathway of infection. That this rule is liable to exception is probable, but that it holds true in a great majority of cases is certain. As in the treatment of Eustachian inflammation we find it of the utmost importance to cure a coincident and predisposing pharyngitis, so it is of equal importance in the treatment of salpingitis to cure the predisposing endometritis. Negative antiseptic cataphoresis meets the indication in these cases better than any other means with which I am acquainted. Negative cataphoresis is to be perferred, because it promotes drainage and depletion, which, on the contrary, positive cataphoresis rather hinders. Antiseptic drainage and depletion of the uterus diminish the inflammatory swelling about the tubal orifices and thus facilitate drainage of the tubes and consequently their restoration to a healthy condition.

If carefully and thoroughly practised in appropriate cases I can conceive of no danger whatever attending negative antiseptic cataphoresis in tubal inflammations after the subsidence of acute symptoms. In cystic salpingitis, whether purulent or not, one would naturally incline to extreme care, if not to absolute non-interference except *per abdominem*, but even here I believe that the dangers of the usual electric treatment have been greatly exaggerated by the surgical exclusivists. Antiseptic cataphoresis may be employed with less local disturbance, and consequently less danger of rupture of the distended tube or extrusion of pus, than attend defecation; yet no one locks up the bowels to obviate this danger.

In the treatment of salpingitis, however, negative antiseptic cataphoresis possesses other advantages. By the cure or amelioration of the endometritis, the likelihood of reinfection of the tubes is diminished, and, in case surgical intervention prove necessary, the physician will not be humiliated and the patient disheartened by seeming failure of the operation due to a residual metritis. Moreover, it is frequently difficult and sometimes impossible to determine how much of the suffering is tubal and how much uterine. Cure of the metritis will solve this difficulty and not rarely save the patient from the well-meaning but intemperate celiotomist. By this method I have treated three cases of salpingitis, two of gonorrheal and one of unknown origin. Of these, one is objectively cured, although she still complains of occasional and slight pain in the region of the left tube; one received but three treatments, declared herself better, and, against my protest, took a journey of a hundred miles by rail—with what result I have yet to learn; the third, of unknown origin and long standing, received four applications, without any noteworthy result, when the treatment was interrupted by my absence, and the patient has not yet returned. In none of these cases was there the slightest untoward symptom in consequence of the treatment.

UTERINE FIBROIDS.—The brilliant results of electric treatment of intra-mural and submucous uterine fibroids have not exempted it from the reproach of an occasional catastrophe. Such catastrophes, however, were very infrequent even in the tentative period of Apostoli's work, and have all but disappeared under an improved technique. I believe that they may be reduced to an absolute minimum by the adoption of antiseptic cataphoresis in conjunction with the precautions usually observed. Why,

it may be asked, are we, in these cases, to disinfect the vagina and cervix and not the uterine cavity itself? Such "disinfection" is ordinarily mere show without substance; for in the first place, microörganisms by prolonged residence in the vagina become "domesticated" and, in a large measure at least, innocuous; and in the second place, pathogenic microbes swarm not only in the uterine cavity, but also in the tubes, in many if not in most cases of advanced fibroid disease. One of the chief benefits of Apostoli's treatment of uterine fibroids is the cure or relief of a coincident metritis. This it would seem, in most cases, constitutes the so-called symptomatic cure. Antiseptic cataphoresis hastens this cure. In addition, it is not at all improbable that by its means remedies may be introduced that will have a regressive influence on the neoplastic tissue. In practice I have used this method sufficiently to be convinced of its superiority, but not to enable me to speak with positiveness as to how much it may accomplish.

DYSMENORRHEA.— Dysmenorrhea depends on a variety of conditions, foremost amongst which is the neuropathic diathesis. Many cases, I believe, are essentially reflex neuralgias akin to trigeminal neuralgia due to exposure of the dental nerve. Here we shall very often find a catarrhal condition of the endometrium and hyperesthesia, especially at the internal os. It is true, as I can testify from my own experience, that excellent results may be obtained by the usual electric treatment. This, however, is inferior to cataphoresis in two respects—the absolute immunity to infection and the speedier relief of the endometritis.

CONCLUSIONS: 1. In the inflammatory diseases of the uterus and its appendages and in uterine fibroids, antiseptic cataphoresis possesses all the advantages of the usual electric treatment, plus antisepsis not only of the uterine cavity but also of the endometrium itself, and, in uterine fibroids, the possible regressive influence of medicinal remedies on the neoplastic tissues. 2. In these diseases it should displace the applicator, injections, caustics, bougies, and all other forms of intra-uterine treatment, with the rare exception of curettage.

ICE IN THE TREATMENT OF CROUPOUS PNEUMONIA.

BY THOMAS J. MAYS, M.D.,

PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC, AND VISITING PHYSICIAN TO THE RUSH HOSPITAL FOR CONSUMPTION.

UNDER the title, "Can Croupous Pneumonia be Aborted?" I contributed a paper to THE MEDICAL NEWS of September 24, 1892, in which are given the histories of two cases of pneumonia treated principally with applications of ice to the chest. Since that time I have used the same method of treatment in a number of other cases, with equal success, and have considered the subject of sufficient importance to institute a collective investigation on a small scale by sending 500 circulars of inquiry[1] to as many members of the profession, so as to ascertain whether my experience with ice in this disease has been or may be disproved or confirmed. I have already received a number of responses to my circulars, which I shall prepare for publication in due time; but before doing so, and in order to make my collective report as full and as conclusive as possible, I am anxious to correct, so far as I am able, the false and unreasonble prejudice that exists against the application of cold in pneumonia—a feeling that I shared myself until I gave the plan a trial—and shall herewith communicate a history of one of my recent cases, the treatment of which has just closed, and which, on account of its interesting course and termination, will, I trust, aid in removing this serious obstacle to the more general use of what I conceive to be a most valuable remedy.

R., male, aged forty-five, was admitted to the Polyclinic Hospital on December 15, 1892, with the following history: He was taken ill with a pain in his left side five days previously. On admission his temperature was 102.6°, his pulse was 110, and his respiration 30; the countenance was flushed; he was restless and delirious; the sputum was rusty and bloody; he had a dry, black coated tongue, a pulse intermittent every fourth beat, and the chlorids were absent from his urine. He had been a hard drinker for twenty years. Physical examination showed dulness extending from the apex to the base of the left lung anteriorly, laterally, and posteriorly. The dulness in the upper anterior half of the lung partook of the nature of flatness. The right lung was normal. Anteriorly there was complete suppression of respiratory murmur in the upper half, and crepitation and partial suppression of respiratory murmur in the lower half; posteriorly in the upper half there were a few moist râles, and in the lower half, bronchial breathing.

His whole left chest was enveloped in ice-bags wrapped in dry towels, and ice was applied to his head on the afternoon of the first day of admission. He was ordered $\frac{1}{20}$ of a grain of strychnine every three hours, and $\frac{1}{30}$ of a grain of the same drug hypodermatically morning and evening, ten drops of the tincture of digitalis every four hours, and three ounces of fresh beef-juice alternately with a glass of milk containing a tablespoonful of whiskey every hour.

On the 17th, two days after admission, the intensity of the flatness of the upper half of the lung had markedly diminished, and the respiratory murmur and very moist crepitation were now heard in this area; the crepitation and bronchial breathing in the lower half not materially changed.

[1] I shall be glad to send circulars to any who want or have not received them.

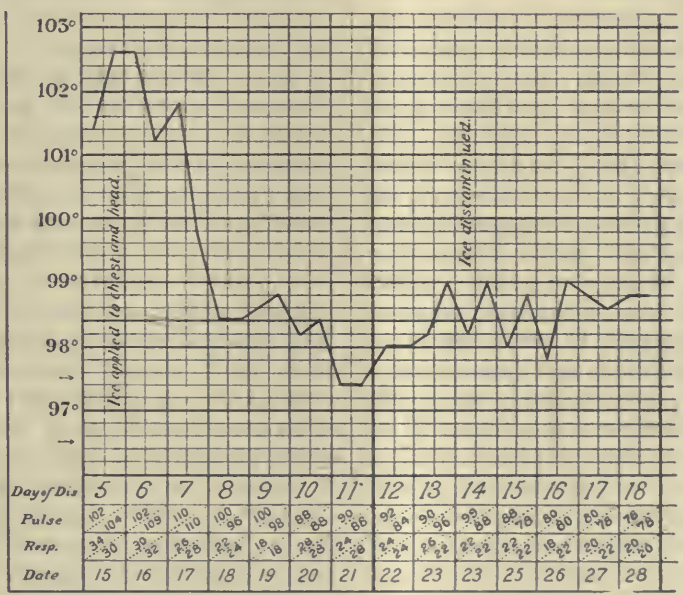
On the 20th dulness had disappeared almost entirely from the lower half, and had diminished very much in the upper half. The last area was now freely permeable to air, and moist crepitant and subcrepitant râles could be heard all over it.

On the 24th the physical signs, except impaired percussion-resonance in the upper half anteriorly, had disappeared, and the ice was discontinued. The digitalis by the mouth, and the strychnine hypodermatically, were also stopped, but $\frac{1}{20}$ of a grain of strychnine by the mouth was kept up three times a day. The beef-juice, milk, and whiskey were continued at longer intervals.

The temperature began to fall on the 16th, the day following the application of the ice, and on the morning of the 18th it was reduced to the normal point, where it practically remained. The sputum continued rusty, bloody, and copious for one week, but the pain and cough subsided soon after the ice was applied. The breathing also became much easier.

On the afternoon of the 18th the low muttering delirium and picking at the bed-clothes, symptoms which were strongly marked in this case, gave way to a most violent attack of delirium tremens. This became so active that it was necessary to strap the man in bed for twenty-four hours, and under the liberal appliance of morphine, potassium bromide, sulfonal, and whiskey the attack was subdued in about forty-eight hours, and after this he made an uninterrupted recovery.

The accompanying chart illustrates the temperature, pulse, and respiration rate of the case.



This case presents several features upon which I shall in conclusion take the liberty of making a few brief comments.

1. *Prognosis.* Without claiming too much it may be said that this was unfavorable. Every-day experience teaches that the alcohol-habit creates a predisposition to pneumonia, and that alcoholism is one of the gravest complications of the latter disease. When this condition is taken in connection with the delirium and the picking at the bedclothes it is quite certain that the prognosis was not reassuring in this case.

2. *The resolving power of the ice on the pneumonic exudation.* It is of course well known that cold has the power of contracting the bloodvessels, and with this view of its action it is clear how ice is capable of dissipating an engorged state of the circulation such as is found in the early stage of pneumonia; but when it resolves an inflamed area which, from the absence of the respiratory murmur and the presence of the flat percussion-note, it is quite certain had passed beyond the stage of engorgement and into that of exudation, we are more or less at a loss to account for the mode of its operation. I must confess that the lateness of the time at which the ice was first applied made me very doubtful whether it would have the least influence on this (upper) portion of the lung, and I therefore relied chiefly on its power to check the extension of the disease in the remainder of this organ. That it had this action was well evidenced two days after it had been used, when moist crepitation and the respiratory murmur appeared, showing clearly that the air vesicles were freeing themselves of exuded material and that air again had access to them.

3. *Influence on the symptoms.* In most of the cases that have come under my observation, the pain, difficult respiration, cough, and expectoration so constantly associated with pneumonia were all notably

relieved in a short time after the ice was applied. This alleviation was very pronounced in the case under consideration. Very often it is this feature of the treatment that makes it acceptable to those patients who yield to it at first under strong protest.

4. *Value of strychnine.* The value of strychnine in the treatment of pneumonia has been well demonstrated by Brunton and others, but its efficacy lies only in the administration of large doses and in its being pushed to the point of its physiologic action. When given in this way it is infinitely better than digitalis—in fact, I think the usefulness of the latter drug in pneumonia is greatly over-estimated, and its supposed benefit is founded on a spurious pathology. By the mouth and hypodermatically this patient received nearly half a grain ($\frac{7}{150}$) of strychnine daily for five days with good results. It is needless to say, however, that if he had not been a chronic alcoholic the physiologic limit of the action of the drug could have been reached by giving smaller doses—say from $\frac{1}{20}$ to $\frac{1}{25}$ of a grain every three or four hours, with an extra daily injection of $\frac{1}{30}$ of a grain.

Details of treatment. Surround the affected area, front, side, and back, with rubber ice-bags well wrapped in towels, continuously. Care must be exercised to prevent the ice-bags from leaking, and from moving away from the chest. Place an ice-bag on the head. Give from $\frac{1}{20}$ to $\frac{1}{25}$ of a grain of strychnine, by the mouth, every three or four hours, and an injection of $\frac{1}{30}$ of a grain of the same drug once a day until its physiologic action becomes apparent in restlessness, which may, perhaps, be first observed in the lower extremities, the reflexes of which are usually enhanced. Give morphine hypodermatically to produce sleep, and three ounces of freshly expressed beef-juice[1] alternately with a glassful of milk with whiskey every two hours. If the stomach is rebellious give the beef-juice, milk, and whiskey by the rectum. A tablespoonful of beef-powder in chocolate or coffee is a most valuable food in these cases when given every three hours. In the convalescent stage I have found the following formula very serviceable:

℞.—Strychninæ sulph. . . . gr. 1½.
Syr. acidi hydriodici } āā f℥ij.—M.
Syr. hypophosph. }
S.—One teaspoonful four times daily.

The Medical Week, the first number of which appeared December 2, 1892, is the name of the English edition of *La Semaine Médicale.* A Spanish edition—*La Semana Médica*—is also published.

PLASTER-OF-PARIS IN ORTHOPEDICS.[1]

By A. J. STEELE, M.D.,
of St. Louis;
Professor of Orthopedic Surgery, Missouri Medical College; Orthopedic Surgeon to the Martha Parsons Free Hospital for Children; President of the American Orthopedic Association.

Last year, in my review of the orthopedic work of the late Mr. Thomas, I observed how rarely, if ever, he made use of plaster-of-Paris. I do recall one instance, however. It was when the wire cuirass that he suggests for the treatment of Pott's disease was shaped over a plaster cast of the patient's back. Doubtless, some convenient Italian was called in to do the work. Had Mr. Thomas's armamentarium been enriched with gypsum in its manifold applications, even he might have done better work and obtained still more brilliant results. Nor do those of like limited practice, as was his, realize what a valuable agent is to be found in this article for immobilizing joints, and for retaining parts of the body in improved position after forcible rectification.

The property of rapidly hardening, when once wet, gives to plaster its value. Additionally, it has merit in its cheapness and convenience. It is ever ready, is easily prepared, and simple in its application. Its use renders the surgeon, in many instances, quite independent of the commercial instrument-maker, a consummation devoutly to be wished, for the latter too often assumes the rôle of doctor, both advising and applying the remedy; without anatomic or pathologic knowledge, and too often without judgment, he applies a stereotyped machine, charges generous prices, and consumes for the patient golden moments, when correct treatment, directed by the intelligent surgeon, could have saved a limb or prevented a deformity in a child otherwise doomed to a life-long disfigurement. These proprietors of surgical-instrument shops are as culpable as the class of prescribing druggists. By their illustrated advertisements, and display of showy apparatus in shop-windows and at public fairs, the people are impressed with the idea that to them they should apply for relief. The profession itself merits a share of blame in this matter. Its members having cases of deformity too often very willingly turn them over to the instrument-maker for apparatus, without having any idea of what is best suited. In fact, having pocketed the consultation-fee, they are glad to get rid of cases about which they know but little, and with which they do not care to be troubled. The set appliances which these mercantile surgical-instrument men handle are very like the patent medicines which can be used without the aid of a doctor.

A better day, however, is now rapidly dawning,

[1] Read before the American Orthopedic Association

when the people, as well as the general profession, are beginning to understand that the successful treatment of deformities, in their intricate and chronic peculiarities, requires the intelligent guidance of specially educated and experienced surgeons. The advanced work of this Association, in correctly educating the profession in these matters, is redeeming the poor cripples from the unprincipled hand of charlatan and mere mechanic.

Welcome! say we, to the intelligent and skilled artisan that can fashion the willing steel according to the ideas of the orthopedic surgeon. He becomes our right-hand man—like the pharmacist to the physician, valued when needed. It is, however, always better if the surgeon can do his own work, for he best knows what is required. Thus, the intelligent use of plaster-of-Paris often renders us independent of the machinist. With it we accomplish good results, and cheaply, too—economizing time and the patient's money. With its use there is no interruption of treatment for repair of broken braces, often a serious matter to the country practitioner far removed from the urban instrument-maker.

We, as surgeons, are largely wedded to methods that have been taught us and with which we are most familiar. Thus, a few orthopedists limit themselves to steel bars and leather straps, ignoring the use of plaster because unfamiliar with its manifold virtues. I, however, opine that all those now entering the orthopedic arena will, among other accomplishments, be expert in the use of the plaster bandage.

Those of us who employ this bandage differ in some of the minor details of its preparation. Thus, not a few prefer crinoline into which to rub the plaster, some previously removing its starch by washing. Individually, I prefer the so-called butter-cloth, Holstein brand. It is more open-meshed than the cheese-cloth, and nearly as much so as the crinoline, and its cost is one-half of that of the latter. Bought by the bolt, it may at once be cut into convenient widths at the bookbinder's, or in twenty-yard folds with a sharp cobbler's knife, on a cutting-board, against a steel straight-edge, or square. Three-inch and four-inch strips are none too wide for application to the trunk; they may be narrower for the limbs, and still more so for infant feet. These strips are cut in desirable lengths; here, again, longer for the trunk and shorter for the limbs. This can be done as each individual strip is being sprinkled with fresh dental plaster, which is most economically purchased by the half-barrel, and is also to be had in two-gallon covered tin buckets.

For preparing the bandage we may use any one of the ingenious plaster-bandage rollers found in the shops. But, if we do, we will probably return to the hand for sprinkling, rubbing, pressing, and loosely rolling the strip. This is best done on the table-top, entirely covered with a piece of stout wrapping-paper, which is afterward gathered up, and the loose plaster shaken into the large tin-bucket plaster-holder, then folded and put away for future use. With proper care no scattering of plaster need occur. For the same purpose, also, Doctor Weigel has devised a board with slightly raised sides, a box filled with plaster being attached to one end, through which the bandage passes while being rolled off the board with the hand.

The rollers are put away into a tight tin can, and kept in a dry place until needed. When required for use they are soaked in warm water. As my own are tightly rolled, I keep three or four soaking during the application, always placing the last one in the water farthest removed from the hand, that they may be taken out in the order of their placing. A pinch of salt previously dissolved in the water hastens hardening when desirable, but increases the brittleness. I rarely employ it except when making moulds.

In applying the bandage, much tension should not ordinarily be used, as some unevenness thereby results, with consequent discomfort to the patient. Each round is made to overlap its predecessor one-half its width, and is rubbed smooth. Reverses are rarely required. The plaster is not applied directly to the skin—a shirt, a stocking, a flannel, or sheet-cotton bandage being interposed. A few moments suffice for hardening, when, as a result of the application, we have a firm, fixed dressing. Should it be desirable to remove it at once, a pencil-mark is made in the line of proposed separation, and with an ordinary pocket-knife a V-shaped groove is cut the whole length of the splint. By inserting the index-finger of the left hand under one end of the splint, the plaster, with the lining, can be completely divided without touching the skin; or a corset-steel may be passed under, next the skin, and cut down upon; or, preferably, an instrument such as I have devised may be used. This consists of a small steel plate, half an inch wide and two inches long, fixed on its flat upper surface to a handle. This surface is plated with zinc, so that the knife-blade may not be dulled as it cuts down upon it.

The plaster splint having been cut nearly through by a gutter-shaped incision, V-like, the flat blade of of the instrument is slipped under the plaster next to the skin, and is cut down upon with a sharp knife, and slowly advanced until the whole is divided.

A freshly-applied splint cuts readily, whereas an old splint may be so hard as to require softening. For the latter purpose nitro-hydrochloric acid was

formerly advised, but it is unnecessarily strong, and might burn the patient's skin. I find vinegar, ever at hand, sufficiently strong to soften the plaster, which may be freely scratched with a knife-blade in the line of proposed incision, and the vinegar plentifully dropped on with a pipette. Very soon

Fig. 1.

Skin protector; used in cutting off plaster splints.

the plaster is sufficiently soft to be cut. Various shears and saws have been devised for dividing the plaster. One form of the latter, suggested by Dr. Meisenbach, consists of two equal-sized saw-blades, shaped like the Hey's saw, three-eighths of an inch apart, and parallel, and attached to a strong handle.

In use it not only divides the plaster, but removes a strip, three-eighths of an inch wide, so desirable when the splint is to be reapplied, that it shall be tighter. Both plaster splints upon the limbs and plaster jackets upon the body become loose and fit less snugly after being worn awhile, from atrophy of the soft parts. One of the blades of this saw can be removed by loosening the thumb-screw, shown at the side, and thus be used to make a single cut. It is unnecessary to soften the plaster when a saw is used.

For dividing splints, however, I prefer a sharp pocket-knife, a little vinegar, and my skin-protector. Some fancy a hooked knife-blade shaped like a gardener's pruning-knife, but this cuts only on the point and is likely to wound the skin.

Fixed splints that have been made removable by cutting may be bound on the edges and fastened with hooks or buckles, or with an ordinary roller, and thus taken off and replaced at pleasure.

The plaster bandage is not only useful for making splints, but also for taking moulds of any part of the body. The part being covered with some light, snug-fitting stuff, the wet bandage, well soaked, is applied loosely, without tension, as otherwise ridges will be made and unevenness result. The bandage is allowed, so to speak, to adapt itself, and is smoothed down with the hands and gently forced into any depressions. Less plaster is used than in the case of a permanent dressing. In a few moments this incasing splint is sufficiently hardened to be cut off in a manner already suggested; the shirt, stocking, or whatever was used to cover the skin being removed with it and becoming its lining. The more sleazy this material the better, for it adheres the more closely to the inner surface of the mould. While I so advise, yet it is not absolutely necessary that any material should cover the skin, for the plaster bandage may be applied directly to the part if previously well soaped or greased; but in this case so fine a surface is not given to the resulting cast.

After removal, the cut edges are nicely adapted and the mould is wound around with twine. So rapidly does the plaster dry that one may proceed directly to make the cast, or the mould may be laid aside for future use.

The line of union of the cut edges is stopped with fluid plaster applied to the outside, and, if it is a body mould that has been made, the lower open end is placed on a rough board and stopped around on the outside with plaster. Then ordinary commercial plaster, mixed with water in a large earthen bowl to the consistency of cream, is poured into the mould. This is to be repeated as often as is necessary until the mould is full.

If the cast had been made on a smooth surface—a table-top, for instance—the mould would not have

Fig. 2.

Saw, double-bladed or single-bladed, for dividing hard plaster.

adhered, but as the fluid plaster was poured in would have risen up, allowing escape at the bottom. The rough, sawed surface of a pine board affords strong attachment for the plaster, thus precluding such an accident.

If a cast of the trunk is being made, plaster can be economized and the cast made lighter by forcing down into the center of the fluid plaster round tin cans. Casts of limbs are made solid, and are strengthened by bundles of wire or several iron rods passed through them lengthwise. One end—the lower—is closed by tying over it rubber or other cloth previously to pouring in the plaster. In half an hour or more the plaster will have set sufficiently to allow removal of the outside mould. A sudden force readily separates the cast from the board. The plaster that was used for stopping the line of junction is now chipped away, and the mould, with its lining, is easily peeled off, leaving the cast intact. There is rarely trouble because of the plaster of the cast adhering to the inside of the mould. Did one fear such a contingency, smearing the inside of the mould with lard previously to filling would prevent it. The cast requires pointing up, and if desirable, may be reshaped, adding here and taking off there; this is best done at once, while the plaster is still moist and comparatively soft. The thin and sharp blade of an old case-knife answers as a tool, though other instruments made especially for the purpose can be found in the shops, and are convenient.

Casts made as thus detailed answer all purposes except when great hardness and toughness are required—when, *e.g.*, they may be subject to the blows of a hammer as in shaping the wood and glue jackets. In such case finely picked tow is thoroughly incorporated into the fluid plaster, and the inside of the mould (probably of the trunk) is smeared all around with it to the thickness of three inches, more or less. On removing the outside casing or mould there remains a light but very tough cast.

Casts are desirable either for preserving the form of a distorted part or to furnish a basis over which to shape splints. There is scarcely a deformity that cannot be well taken in this simple manner, and I cannot too strongly urge the importance of obtaining and keeping casts of our deformed cases, especially the rare ones. They have a place in the history of the cases and are valuable for illustration and instruction. None should be deterred from attempting to make them; the process is so simple and rapid that anyone may soon become an expert, whether the cast is made as above detailed or after the older methods of pouring fluid plaster directly upon the skin, previously well oiled or soaped.

Dr. Whitman, in making a cast of the foot, the toes excepted, suggests that thickly mixed plaster be poured upon a square of cotton cloth, and the outside of the foot be allowed to sink into it; the edges of the cloth are then raised until more than one half of the foot is covered; when this is hard, vaselin is spread on its upper surface, and the exposed portion of the foot covered with more plaster. When hard, the two halves are taken off, bandaged together, and the interior, previously oiled, filled with fluid plaster. The outer shell being removed, a cast is obtained of the foot.

A few words may be added as to the employment of the plaster bandage in various affections and in different regions of the body. Gypsum had been recommended by Mathiesen of Holland as early as 1852, as a convenient material with which to treat fractures, but the plaster bandage was first employed for the relief of a deformity in 1875, the affection being Pott's disease; and it still holds its place as an economical and efficient support to the body in spondylitis, especially of the lumbar and of the lower and mid-dorsal regions. The novitiate in its use finds trouble in the ulceration or excoriation of the skin that often occurs over the boss; to prevent the undue pressure and friction that cause this, I cut an oblong opening in a sufficiently thick piece of boiler felt, and place it over the projecting spinous processes, care being taken that it does not shift as the bandage is drawn around and over it. Boiler felt also makes efficient pads for the hip-bones in adult patients. Usually the plaster jacket is made to extend above not higher than the axillæ; but if the disease is in the cervical or upper dorsal region, more thorough support can be obtained by carrying the bandage above the shoulders, like a vest. I cannot say whether or not I was the first to adopt this plan, now some twelve years since, but certainly support for three or four additional vertebræ can thus be had; and with the disease in the cervical region the bandage has been carried still higher, up the back of the neck and around the head. To additionally strengthen the jacket I fortify it with strips of galvanized-wire gauze, the size and strength of the strips depending upon the age of the patient; the corners are cut off and the edges bound with sticking-plaster. The plaster is better incorporated with the gauze than with perforated tin.

In lateral curvature a plaster jacket or corset gives support and comfort, but is not used as a corrective of the deformity.

The use of the plaster bandage has, within the past dozen years, almost revolutionized the treatment of club-foot. Through its aid we now do at one sitting what formerly required many weeks. Under an anesthetic the foot is at once straightened, with or without tenotomy (according to the age of the patient), and so held by the plaster, a sheet-cotton roller having been previously applied to the part.

Here again I find valuable aid in a strip of wire gauze: a layer of plaster bandage having been placed over the foot and leg, one end of a narrow gauze strip is carried around the foot, and while it is forcibly held in corrective position, the other end of the strip is carried well up the outside of the leg and there fixed with additional rolls of the bandage.

In hip-disease, the joint may be quite efficiently immobilized by a plaster bandage carried well up on to the trunk and down to the lower third of the leg. This is a ready method for the country practitioner far removed from the instrument-maker, or when economy is necessary. This bandage, however, finds more suitable adoption in the immobilization of the knee-joint. The limb being covered with a long stocking or drawer leg, and the articulation surrounded by cotton, the plaster is carried well up on the thigh and down upon the leg, and fortified with metal gauze strips on the sides, thus affording a cheap and efficient splint. If, however, the patient is much on his feet, the splint tends to drop—to become displaced downward. This may be prevented by giving it support through a steel arm extending to the sole of the shoe, or it may be suspended by straps from the opposite shoulder. I have also to good purpose used a piece of adhesive plaster for fixing the splint to the skin of the leg at the time of application.

In disease and sprains of the ankle-joint, plaster finds frequent and admirable application, care being taken that the foot is put up at a right angle—not extended.

The gypsum bandage is applied to the elbow-joint and the wrist-joint for immobilization, meeting well the indications. Care is exercised here, as whereever the plaster bandage is applied, that it is not wound around the part so tightly as to produce undue constriction and interference of the circulation, with consequent sloughing. The appearance of the part beyond the bandage, as of the fingers or the toes, will indicate danger by coldness, swelling, and discoloration, in which event the plaster should at once be cut off. A case of malpractice is now pending in our courts in which a doctor applied a plaster dressing to a boy's arm for a fracture extending into the elbow-joint, and extensive sloughing of the tissues of the forearm followed.

In both in-knee and out-knee, and in tibial curves after forcible manual correction or after osteotomy, the plaster splint holds the limb in the desired position until union takes place in the second case or accommodative changes have fulfilled the indications in the first. In manual correction of genu varum or valgum I change the splint every three or four weeks. In wry-neck, after myotomy and subsequent rectification, the bandage from a body-jacket is continued up the back of the neck and around the head, thus firmly holding the parts in the corrected position.

Having subcutaneously tapped a ganglion and scarified the interior of the sac with a spear-pointed instrument, like a couching-needle, and effectually expressed the contents, I apply a firm pad, and put up the wrist in a flexed position, with a plaster bandage extending down the forearm and including the hand. Obliteration of the ganglion universally follows.

I might multiply the instances in which the gypsum bandage finds admirable and convenient application, but will rest with the suggestion, that as one becomes more expert in its use, the more often he will find occasion for it.

ORIGINAL ADDRESS.

VALEDICTORY ADDRESS.[1]

BY ALFRED L. LOOMIS, M.D., LL.D.,
OF NEW YORK.

Fellows of the New York Academy of Medicine: Before I pass to my distinguished successor the insignia of office with which you honored me four years ago, it seems fitting that I should review in brief the work of these years, that we may the better appreciate the rapidly increasing breadth of our fellowship, and recognize that privilege and obligation are twin sisters in their growth.

The story told in dates and figures alone might be cold and formal, but the ratio between 640 and 270 bristles with interest when each unit means a Fellow and we recognize that the new members received in four years equal more than 33 per cent. of our entire membership so short a time ago. And interest passes to pride, when among the new faces we see so many of the older members of the profession whose honorable positions and intellectual work have brought us both strength and renown. Nor is our pride without hope for the future. Among the younger members who now share our fellowship are found many of the most active workers in the profession, not a few of whom have already gained honorable distinction for work done. Every line of our growth is marked by equally eloquent figures. The 7000 new volumes and the 2000 new pamphlets which already crowd our present shelves to overflowing, and have raised the catalogue of our library to 27,000 volumes and 8500 pamphlets, represent but a slightly lower per cent. of increase. The breadth of privilege which these figures indicate cannot be made more clear, nor is it possible to obscure the twin, obligation. Men and books are valuable only when combined with mental processes. How faithfully we have met this obligation is shown in the fact that the number availing themselves of the privilege of our library has increased in three years 350 per cent., while men and means have increased one-third. The work done in our library has increased three and one-third times. These figures gladden our hearts, for they indicate that our fellowship is

[1] Delivered before the New York Academy of Medicine, Jan. 19, 1893.

doing ten times more brain-work than it did four years ago, its intellectual status is being elevated, and a deeper enthusiasm and stronger purpose is giving more certain relief and comfort to suffering humanity.

It may not be uninteresting to recall the more material side of our history in these harvest years.

In 1888 we held a clear title to the Academy building in Thirty-first Street, which was valued at $60,000, and our building fund had reached $96,000. Under the stimulus of Dr. Jacobi's enthusiasm there had been many discussions in both Academy and council regarding the immediate necessity of a new Academy building, which finally crystallized at the regular meeting of October 18, 1888, into the unanimous passage of the resolution "that in the opinion of the Academy it is now expedient to take active steps toward the purchase of a site and the erection of a new Academy building." The trustees and council were instructed to carry out the intents of this resolution. Owing to unexpected complications it was not until March 7, 1889 that the council reported to the Academy the execution of a contract for the purchase of a site on West Forty-third Street, at a cost of $90,000. Formal authority to draw upon such funds of the Academy as could be legally used for that purpose was conferred upon the trustees by vote of the Academy at the meeting of April 14, 1889, when a special building committee, composed of Drs. Jacobi, Herrick, Peters, Castle, and Loomis, was appointed and intrusted with all matters of detail. Two months were spent in consideration of plans and designs, and on June 4, 1889, the Academy accepted unanimously those of Mr. Robertson, which the building committee had submitted as having their approval, and authorized the committee to make contracts for the erection of a building in accordance with these plans, and under the supervision of Mr. Robertson, as architect. These instructions were obeyed with the least possible delay, and on October 2, 1889, less than one year from the date when the Academy assumed a definite position on this question, the corner-stone of this building was laid with appropriate ceremonies. At the end of another year your building committee formerly transferred this completed building to the board of trustees.

The anniversary meeting of November 20, 1890, was made memorable by the dedication of the most complete and appropriate building of its kind in the country, and the formal opening of its library to the profession and the public. It was an occasion which will be long remembered, not alone by those present, but by all who appreciate the full significance of the event; when distinguished members of our profession from neighboring cities, and eminent citizens of our own city, who had given generous proofs of their sympathy, united in celebrating the consummation of our long-cherished hopes.

Never was there more beautiful illustration of the truth that, to earnest men, the end is but a new beginning, than in the spirit of all that was said or done on that occasion. Our anniversary orator looked backward only to see in the zeal which had attended our growth from the first, the promise that our Academy was to go forward in the future to enlarge in generous measure her chosen work, and consummate her functions, sustained by a common impulse among her Fellows to work for work's sake.

That eloquent champion of our library, your honored ex-President, Dr. Jacobi, saw in this building no home for lotus-eaters, but the visible vestibule for a new epoch in medical learning and achievement. His strong words found faithful echo in the trembling accents of our honored, our beloved Barker. With the dawn of another life already tingeing his horizon, his prophetic promise to this Academy of a new era, so full of grander things, that none would venture to cast a horoscope of its future, was spoken in tones that almost made real the spirit of "Now, Lord, lettest Thou thy servant depart in peace," nor were such conceptions distorted images of blind affection.

In the communication sent us by our noble and generous friend, D. Willis James, were these words, which should be repeated to every large-hearted citizen of New York: "Look at the magnificent work the medical profession has done and is doing. Remembering all they have accomplished for suffering humanity, let us, as citizens of New York, see to it that in our midst the means are ample and promptly supplied for the most scientific research in all departments of learning, but especially in medical science."

That full appreciation of our profession is too often lacking when most expected, must be confessed with sorrow, for Weir Mitchell told us that although the medical guild possessed a high code of morals, which was old before Christianity was born, a code based on honor, loving brotherhood, and the largest charity, even when made practical in self-sacrifice, it has never been fully appreciated even by the recipients, else would they be more eagerly generous in their assistance in building halls and furnishing libraries.

The old but ever new spirit of our profession, which has borne it onward and upward, regardless of rewards, was most beautifully portrayed by our loved and honored brother, Oliver Wendell Holmes, who wrote in his greeting for that night: "An academy which fulfils its highest function is a true working body. It deals with loving subjects. It handles unsettled questions. It sets tasks for its members and furnishes, so far as it can, the appliances required for their accomplishment. It offers rewards for meritorious performances, and sits in judgment on the aspirants for distinction. It furnishes the nearest approach we can expect to a fixed standard of excellence by which the work of new hands, and the new work of old hands, can be judged. It is a barrier, a breakwater, against the rush of false pretensions which are constantly attempting to find their way into public confidence. Academies have been too often thought of as places of honorable retirement and dignity and ease, nooks where emeritus professors and effete men of letters, once cocks of the walk, could sit in quiet roosts while the fighting, the clucking, and the crowing were going on beneath them."

With such words of cheer and sympathy, of promise and prophecy, of warning and advice, amid the gracious smiles of approving friends, this building was dedicated a little more than two years ago. Experience has shown it in every way suited to our wants and work, and from the day of its dedication until now, not only has prosperity attended us, but a broader and more tolerant spirit has been developed in our membership. The links which bind together the

senior and junior members of our fellowship have grown stronger; jealousies and intolerance have given place to liberality and kindness, and the Academy has become the center of the best thought and the best spirit of the entire profession. The young enthusiast and the aged conservative are crossing swords with that spirit of modest recognition of truth in which one scientific worker is always willing to meet his fellow. We are to-day exerting a greater influence on public thought and action than ever before. We are being more and more appealed to in the legislative and economic work of the Commonwealth. The public health and safety of our citizens are being more and more committed to our hands. Last summer, when our city was threatened by the invasion of a pestilence, the whole community looked to us for protection, and through the governing body of our nation's commerce, appealed to us for advice and guidance. Do you realize, gentlemen how large a feeling of safety comes to the public on account of the presence of the Academy in the midst of our city? Let us act wisely and unselfishly in all matters pertaining to the public good.

In our first appeal made to the profession and public to erect a new and more commodious Academy building, it was stated that our most pressing need was a suitable place for our library.

Expressive as they are, the figures which I have given you of the library are but lifeless proofs of the eloquent words spoken by Dr. Jacobi at the laying of the corner-stone, and with increased fervor at the opening of this building—prophecies which are rapidly being fulfilled. The real influence of our library is in the intellectual development of our fellowship, which cannot be measured by figures, but must show itself in the more exhaustive and accurate work done by our members.

But it must be remembered that the cessation of growth is the beginning of regeneration. If we are to go forward, our library must not fall behind. Its endowment fund is now only $25,000. It should be increased at once to $100,000; with no less a sum can we keep pace with the present tropical growth of medical science. That some of the large-minded men with ample means will soon discover their privilege is no longer a matter of hope but of certainty, for money in no other place can exert such a constantly widening influence for good, as the increase in our library endowment fund to the sum of $100,000.

There are not a few in our midst to whom the entire sum seems small, and I would say to those who would share this honor and receive a monument of gratitude, more enduring than marble: Do not delay lest the opportunity be lost. The bronze in yonder tablet was bought for a few dollars, and on its face it simply says, "This man built a hall;" but let me say to those who hear or read these words that this man's name will fall from reverent lips in tones of love and honor when all marble piles are ground to dust.

With our library fund raised to what it must be, our strength would be complete, for all the departments of medicine and surgery are now represented in our sections, so that every Fellow can find a place among congenial workers for making known the results of his study under the sifting but kindly criticism of experts.

The plan by which the general meetings of the Academy each month are placed in charge of the sections in rotation, thus presenting to the Academy the special work being done in them, has not only added interest to the Academy meetings, but has developed a spirit of generous emulation under which all the work has become more systematic; and sections that four years ago were indifferently attended, doing desultory work, have now become active and efficient parts of our organization. The fear that increase in the number of sections would diminish interest in the general meetings has proved groundless, for the attendance at both the Academy and the section meetings has increased rather than decreased.

These evidences of a broader and a deeper scientific spirit doubtless give promise of better things to come; when we appreciate that no hampering debts can distract us from our higher purpose, we enter upon our future not only free from debt, but full owners of a building worth $380,000, with furnishings representing $30,000, a growing library valued at $80,000, and invested funds over and above the $10,000 bonds still uncancelled, to the amount of $32,000, making a total of more than half a million. With such a financial status and such a fellowship, the question comes to us to-night—What is the mission of the New York Academy of Medicine?

At the laying of the corner-stone of this building Mr. Cleveland said that "The nobility and sacred character of this mission will never lose its interest, while humanity is touched with human woe; while self-sacrifice receives the homage of Christian hearts; while the suffering and sorrows of our fellow-men start the tears of pity; nor while their alleviation brings comfort and satisfaction to the soul of sympathy." This broad and clear conception of our mission is from a layman's standpoint, but represents work done, not doing. For us the question is one of ways and means, of obligations that are individual and collective. To the individual Fellow we offer opportunities and means for a richer intellectual development and social culture, and justly demand that he use them for his own and our common good. No Fellow has a right to ignore this obligation of fellowship, for the Academy stands before the public for what its individual Fellows may be. For us, obligations and rewards are reciprocal. Whoever shares in honors won by others is bound to make return to the best of his ability.

To everyone the first duty is a recognized connection with one or more of our sections, a connection which imposes the obligation to attend its meetings when possible, to pursue studies and investigations that shall be worthy the attention of the section, to give encouragement and support to fellow-members by serious and earnest consideration of the subjects they may present.

As an organized body we have no more imperative duty, or one requiring greater wisdom, patience, perseverance, and courage, than in organizing and harmonizing medical work. It is worse than folly to shut our eyes to the fact that so large a per cent. of medical work is done to fill time as well as space, as to become a matter of jest and sarcasm even among ourselves. It is worse than cowardice to confess the impossibility of doing enough good work to satisfy the demands of all

our societies, and then make no effort to correct the wrong.

If I may still be permitted to offer one word of advice from this presidential chair, it would be this: That the foremost duty of this Academy to-day, and the one offering in its completion the largest and most valuable returns to us and the profession, is the consolidation and concentration of the medical societies of this city. I do not say this because the many other societies are not doing good work—many of them are doing some of the best that is done—but I do say it because they and we are doing some bad work, because we need their good work as they need ours, and neither needs bad work. In these statements I do not, of course, include the County Society. It occupies a unique position, accomplishes results that we could not accomplish, and possesses functions that cannot be delegated. It and the Academy are complementary bodies. With this exception, then, I am convinced that consolidation of the many small societies with the Academy would be productive of the greatest good to all concerned; that it would do more to conserve energies, to eliminate work that, in being bad, is injurious as well as valueless; to establish higher ideals; to return more generous rewards for work done; and finally, to develop a stronger spirit of common brotherhood than any step which has been taken by the profession. I am unable to see any valid objections to such a union, unless a chartered society holds property accepted under specific restrictions.

The predominance of the social element, which has been advanced as an objection, appears to me a most cogent reason for taking such a step. The introduction of the social element into the regular monthly meetings of the Academy during the past two years, which was made possible by the liberality of some of our Fellows, has demonstrated that the value of the scientific work is enhanced rather than lessened, the discussion of the evening being frequently continued in the groups gathered about the tables. There can certainly be no objection to the addition of the social element, even to the section meetings, whenever the members desire it, and thus fulfil all the claims of the social medical societies.

I cannot leave this chair of office without a word of tribute to the Fellows whom death has taken from us during the past four years; among them are three to whom this Academy will always owe a special debt of gratitude and respect—Du Bois, Barker, Leaming—names which we cannot follow with the hackneyed phrase, "We mourn their loss." As men and friends, the parting brought to each of us in varying measure the aching heart and weary sense of hopeless loss. But to this Academy they can never be lost. The story of their loyalty and devotion, their watchful care and self-sacrifice, their wise counsels and liberal support must continue to exert an influence on every Fellow who values an honorable name. We can pay them no loftier tribute of respect and appreciation than to say, "We do not miss them," for that is the test of a rounded life. We restore the borrowed garments to the earth from whence they came, and call them the man. Why do we thus deceive ourselves? That faithful canvas shows but the house where Barker tarried for a time. Those hands with woman's tender touch were only tools which did his bidding, and when the recreant voice gave halting service and laggard obedience, who thought to say his wit has dulled, his learning failed, his foresight dimmed, his counsel erred, his love grown cold!

These men did all that man can do. They did their part in life with faithful zeal until their powers gave way; and with that wisdom which never dwells in sordid minds, they died, not to leave their mental wealth for legacies, but day by day transferred it to men with fresher strength, and so gave over, not gave up their work, content in the knowledge that it was not to cease, but grow larger year by year; and when at last their summons came, the best of all they had, the essence of the man, his quality, they left with us.

Why is it that we will not see the truth within this mystery of death? We whine in greedy selfishness: "No man will miss me when I die," and will not see the reason that stares us in the face—the useless man receives his share of being missed when living, and cannot ask for more. The man whose worth is sterling cannot be missed; the force that is the man goes on. As we turn our faces to the front, then, let us not forget these present, if unseen, Fellows; but, made stronger in their influence, let us press forward with unfaltering courage and determination to make and share such measure of worth, that we too shall not be missed.

Fellows of the Academy: Four years ago, when you honored me with the presidency of this Academy, I entered upon the duties of the office with a feeling of self-distrust. Two years ago, when you unanimously elected me to a second term, I felt grateful for the renewed expression of your confidence; but when a Fellow at the close of this term nominated me for a third term, a feeling of pride came to me, for no greater honor could have been conferred upon me. In declining the nomination, I realized that the time had come when the interests of the Academy would be best served by new energies stimulated by a fresh enthusiasm. For all your patient courtesy, and the many evidences of respect and confidence shown me during these years, I give you my grateful thanks, with the feeling that another and the most beautiful chapter of life's labor and waiting is ended.

CLINICAL MEMORANDA.

HERNIA OF THE PLACENTA THROUGH THE MUSCULAR COAT OF THE UTERUS DURING LABOR.

BY J. G. LYNDS, M.D.,
DEMONSTRATOR OF OBSTETRICS AND GYNECOLOGY IN THE UNIVERSITY OF MICHIGAN, ANN ARBOR.

MRS. B., thirty-eight years old, a primipara, called me to attend her on October 9th at 5 A.M. On examination I found an enormously distended bladder, upon evacuating which the pains ceased.

About 6 P.M. I was again called, when I found the patient having strong regular pains, and the os beginning to dilate, everything appearing normal.

On making an examination a couple of hours later, I found an enlargement on her left side at the junction of the upper with the middle third of the uterus. It would almost disappear when there was no uterine contraction, but became larger and larger with each succeeding pain.

After watching it for some time I came to the conclusion that it was a fibroid undergoing abdominal evolution, and becoming subperitoneal; and informed the husband and nurse to that effect.

When the head was about half-way through the bony canal it ceased to descend farther, but the tumor became rapidly larger. Fearing some serious complication I applied the forceps and delivered without any great difficulty. I was surprised that there was no hemorrhage at all. After waiting fifteen or twenty minutes I proceeded to deliver the placenta, first trying expression; this proving unsuccessful, I introduced my finger and followed up the cord as far as I could reach, but failed to find its attachment to the placenta. Introducing my hand, I found that the cord passed through an opening on the left side of the uterus at about the junction of the upper with the middle third of the organ. With difficulty I insinuated a finger and found the attachment of the cord. The opening was very small, only permitting the admission of one finger beside the cord. Thoroughly anesthetizing the patient, I dilated the opening and endeavored to remove the placenta, but found it very firmly attached—so much so that it tore in many pieces in the process of separation. Finally I succeeded in getting it all away and emptying the uterus, the walls of which were very thin. As the organ soon filled up with blood-clots and became about as large as before the placenta was removed, I again thoroughly emptied it, and by bimanual pressure kept it contracted until hemorrhage had ceased. The patient made a very fair recovery. She had some slight symptoms of peritonitis, but nothing of a serious nature. The cause of this odd occurrence must have been a peculiar arrangement of the muscle-fibers, in consequence of which they drew apart at this particular place, leaving an opening through which the placenta escaped, pushing before it the mucous membrane.

A CASE OF HOMATROPINE SUSCEPTIBILITY.

BY GEORGE M. GOULD, A.M., M.D.,
OF PHILADELPHIA.

I LATELY had a patient, a lady, thirty years of age, who showed an extreme idiosyncrasy as regards homatropine. For purposes of mydriasis I dropped into each conjunctival sac a tiny drop of a solution (Merck's manufacture), gr. viij ad ℥j, four times at intervals of from five to ten minutes. I habitually instil only a portion of a full-sized drop, by extruding this amount at the end of the dropper and lightly touching the conjunctiva with it. The entire eight droplets would consequently not equal more than one or two of the usual size. In consideration of this fact, and also deducting the amount wiped away with tears or otherwise not absorbed, the total quantity of the drug absorbed must have been infinitesimally small. The following morning the patient's lids were swollen almost shut, and the cheeks for two inches below the eyes were puffy and highly discolored; the skin of the back, chest, arms, and legs was erythematous, and there was general prickly heat with great itching. The effects passed off in twenty-four hours. The patient informed me that similar symptoms had several times resulted from the use of belladonna plasters.

If we liberally suppose that two full drops of the solution were absorbed, it follows that about one-thirtieth of a grain of homatropine produced the effects described.

MEDICAL PROGRESS.

The Prognosis of Actinomycosis.—SCHLANGE (*Archiv f. klin. Chirurgie*, xliv, 4, p. 863) concludes an analysis of sixty cases of actinomycosis of various organs and structures by formulating the prognosis. When the disease involves the head and neck, except in the few cases in which the base of the skull is invaded, the course is favorable, recovery taking place in from a few to nine months; it is exceptional for a fistula to persist or to have formed anew after the lapse of a year. Pulmonary actinomycosis, heretofore considered necessarily fatal, may terminate in recovery. The prognosis of intestinal actinomycosis is the more favorable as the anterior abdominal wall is involved and the retro-peritoneal structures escape. Retro-peritoneal extension of the disease renders unfavorable the local conditions facilitating the expulsion of the fungus; death usually results from amyloid degeneration and wasting. If actinomycosis present pyemic manifestations a fatal termination is to be expected, as a number of vital organs are likely to be involved. Actinomycosis may pursue a chronic course, continuing for thirteen years or longer, if functionally important organs be not involved, as when the process confines itself to the connective tissue about the spinal column.

Changes in the Fields of Vision in Cases of Traumatic Neuroses.—PLACZEK (*Berliner klin. Wochenschr.*, Nos. 35 and 36, 1892) has reported seven cases of traumatic neuroses, in each of which he found certain changes in the fields of vision that have been described as characteristic. The range of vision was greater as the test-object was moved from the periphery of the perimeter to the center than when moved in the opposite direction. It was also found that concentric limitation of the field of vision was characteristic of the traumatic neuroses, though the symptom could not be developed in all cases.

Mercurial Intoxication.—At a recent meeting of the Royal Society of Physicians, of Vienna, PROF. ALBERT (*Internationale klin. Rundschau*, No. 50, 1892, p. 2043) reported that mercurial intoxication had developed in himself as the result of the frequent use of corrosive sublimate in surgical practice. A considerable quantity of mercury was obtained from the urine of twenty-four hours. The intoxication had manifested itself especially in the form of dyspeptic symptoms; the nails had become softer and tougher, and three sound teeth had fallen out.

The Association of Posterior Spinal Sclerosis and General Paresis.—At a meeting of the Société Médicale des Hôpitaux, RAYMOND (*La Médecine Moderne*, 1892, No. 51, p. 774) reported having found, after death, in the case of a man who had at first presented the symptoms of posterior spinal sclerosis, and subsequently in addition those of general paresis, besides the classical systemic lesions of the posterior columns, meningo-encephalitis.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 21, 1893.

THE SENATE QUARANTINE BILL.

THE quarantine bill passed by the United States Senate is an important protective measure which confers great powers upon the U. S. Marine-Hospital Service, as well as upon the Chief Executive of the Nation. While it does not place quarantine administration absolutely and exclusively in the hands of the National authorities, it virtually has that effect; for it is expressly stated that when at such ports and places within the United States where quarantine regulations exist under the authority of the State or municipality, these regulations are not deemed sufficient in the opinion of the Secretary of the Treasury to prevent the introduction of contagious or infectious diseases into the United States, the Secretary of the Treasury is authorized to make additional rules and regulations to be enforced by the sanitary authorities of the States and municipalities. If the State or municipal authorities fail or refuse to enforce them, the President shall execute and enforce them through officers appointed for the purpose. In other words, quarantine rules and regulations must conform to a National standard, and their execution and enforcement, whether by National or local authorities, are placed under National control.

There is no mistaking the object of the bill as being the ultimate assumption by the National Government of absolute control of quarantine affairs. It is, however, a tentative measure which has merit in avoiding a too sudden change in administration. As a compromise between opposing views, it also avoids antagonism and a revulsion of feeling which a more radical measure might provoke. The main object—the National supervision of quarantine—is secure, and the effects of the law cannot be otherwise than beneficial.

A uniform quarantine service is a want generally felt and acknowledged. And now is the opportunity for supplying this want. It is a question of National concern, and it is therefore right and proper that the Government should assume the duty and exercise the right to legislate upon the subject.

Another very important feature of the bill is that which gives the President the right to prohibit, in whole or in part, the introduction of persons and property from countries or places where cholera or other infectious or contagious diseases exist. The suspension of immigration, under the circumstances mentioned, will go far to diminish the danger of the introduction of contagious and infectious diseases, and greatly strengthen the bill as a protective measure.

The provision of a liberal appropriation is not the least important item in the bill. Parsimonious appropriations to the local quarantine authorities have been largely to blame for the want of proper equipment of the stations and the resulting inefficiency. The U. S. Marine-Hospital Service will, fortunately, not be hampered by this drawback.

It is greatly to be desired that the bill shall pass the House, and that immediate steps be taken to organize the service under its provisions.

HAHNEMANNIAN TENDENCIES AND PRACTICES.

THERE are certain habits of mind and of action that characterize the quack everywhere and at all times, and when the advertisements, claims, and acts of members persistently show that these tendencies are unrebuked by the composite body to which the individuals belong, it cannot be thought an injustice if the epithet of quackery is applied to the entire association. Several suggestive things have of late come to our notice that, so far as we know, have never received a word of criticism or dissent from the better class of the advocates of homeopathy.

The plainest evidence of quackery is the appeal to the public as to the cure of disease. The advertisement in lay journals of ability to cure disease and of superior medical knowledge, is of the very essence of quackery. The great and official homeopathic druggists, BOERICKE & TAFEL, have lately issued a little book, *Safety in Cholera Times*, and from the character of the writing and from the fact of its being advertised in non-medical journals, it is plainly designed for popular dissemination. The appeal direct to popular prejudice and the densest medical ignorance is made most unblushingly and frankly. Here is an advertisement cut from a lay newspaper:

"*The cholera scare is over.* If the public could be brought to realize the safety from the attacks of this disease that there is in Homeopathy, the scare would never occur again. From official reports, covering over a million cases, we learn that the death-rate of the 'regular,' or Allopathic practice in this disease has been (and from present reports is) 54.8 per cent. of the cases treated. The same reports show that the death-rate in cholera under Homeopathic treatment was 8.5 per cent. Under the proper Homeopathic prophylactic treatment, the danger of contracting the disease is almost *nil*. We publish a little book, *Safety in Cholera Times* (50 cents, by mail 54 cents), that gives the treatment of the disease and the preventive treatment. It is worth the money in the peace of mind it affords. BOERICKE & TAFEL, Homeopathic Publishers and Pharmacists, 1011 Arch Street, Philadelphia, Pa."

The "treatment" of the disease repetitively lauded in this unconsciously humorous and crazy book is *Verat.*[30], *Cuprum-metal.*[30], *Carb. v.*[30], and *Camphor*[3]. It matters not that if the patient should eat a bit of toasted bread for breakfast he would thereby take myriads of doses of vegetable carbon which in mystic pellets is guaranteed to cure him. It matters not that the physiologic dose of veratrum or copper is, in this 30th "potentization," diluted as much as if dissolved in a body of water equal in size to 480,769 of our worlds. In the same way, what an insult to popular intelligence is implied in the roaring claim of "cures" of cholera by these or by any means. What fools the Hamburgers were, to be sure!

The use of medical knowledge against the men and the profession that have acquired this knowledge and taught the trickster is another characteristic of the quack. A most excellent surgeon and teacher writes us that for many years it has been the custom of the homeopaths of several States about him to send their sons to his college to acquire the necessary medical knowledge, with no intention that they should subsequently practise scientific medicine. These youngsters, so soon as they get their diplomas, join the ranks of their fathers and at once commence the fight against the "bigoted allopath." Our correspondent says that at a recent convention of homeopaths a number of the most prominent men, as usual, took to raving and fuming over the tyranny of the "old school," its archaic practices and teachings. At the same moment their sons were receiving their entire medical education at a regular or scientific medical college. This throws light on the mental condition of the fellows who "leave the old school," who have "studied both," or who "practise both ways."

This aspect of the affair is indeed but another illustration of the greater fact that not a single truth of medical discovery or progress, not a bacillus, not an instrument of precision or useful method of treatment was ever discovered by a member of this sectarian school. They take the results of the work of other men and use them selfishly, with hatred and abuse of their benefactors. Spongers, all!

A third characteristic of the quack is his disregard as to whether his unscientific fad tallies with the conclusions of other than medical science. There is not a professor of Physics or of Physiology in any institution of learning in Europe or America that would not turn with nausea from the question, if the thirtieth "potentization" of a dose of medicine could *a priori*, or, as a result of tests on animals, have any physiologic power whatever. The assertion is too silly to answer. The same is to be said of the last hommypatic egg, the sacred fiddle-faddle of *similia*. To what scientific pathologist or physiologist is it not the most arrant nonsense? And his nausea would be most active, indeed, if asked as to the lice, the pus, the bugs, and the frightful filth catalogued and to-day on sale by SWAN, the New York homeopathic druggist. TESLA cannot bottle up "blue and yellow rays of the spectrum," but SWAN has them for sale at so much a "graft"—and SWAN is of the purest dye of haloed and hallowed homeopathy.

To choose a final illustration among many other proffered ones, we quote from a recent number of the *British Medical Journal* part of an editorial that at once exemplifies many faces of this protean monster. It is entitled "Electro-Homeopathy, or Hahnemann Harnessed":

"On the principle of elective affinities we are not surprised that a union has been effected between the two 'pathies' which constitute the subject of these remarks. Electropathic and homeopathic systems of treatment are so much akin, both in their origin and direction, that nothing is more natural than to find them in company. 'You air my affinity!' exclaimed the Mormon lady to Artemus Ward, the genial showman, as she flung herself into his arms and protested that the Powers above had decreed their union. Thus to homeopathy comes electropathy, and avows it is her long-lost connection. Mr. Labouchere, in the pages of *Truth*, has told the story of the attachment and the celebration of the marriage of this latest fashionable pair. Mr. Knight represents the institution which in this country has been founded for making known the blessings of a new system of electro-homeopathy. Already the latest of the 'medical sects' (pardon us, shades of the teachers of Alexandria) has its annals and its propaganda; its insignia are a red and blue star, indicative, we presume, of the red and blue electricity with which the soap, the dentifrice and gargle, the lime hair-wash, the velvet powder, and the 'lactescent balsamic bath' are impregnated. No longer is the divinity of electropathy enchained in a belt or a pad, but the liberated goddess diffuses her blessings to mankind by the toilet table and the lavatory. 'Sauter,' says *Truth*, 'appears, as far as I can make out, to have succeeded in bottling up vegetable electricity in homeopathic doses. His remedies, marvellous to relate, will cure all diseases, even those regarded as incurable.' But all this cannot be done without money, and as the poor are to have the blessings of the system without money and without price (we are uncertain whether this includes the soap, the dentifrice, and the lactescent balsamic bath), the charitable are invited to send around the 'snowball,' so that money-orders, checks, and bank-notes may pour into the treasury of the Institute of Electro-Homeopathy, and replenish its funds, which appear at present to amount to £3 4s. 1½d. Thus is Hahnemann harnessed to electricity, and thus has the latest medical discovery blessed the world from without the circle of the orthodox. As Mr. Labouchere has turned the search-light of *Truth* upon the new system, its advantages will probably be completely manifested to such of the public as at present are incredulous."

THE CAUSES AND TREATMENT OF PREMATURE BALDNESS.

SEEGER (*Wiener Klinik*, December, 1892) discusses in a lucid and consecutive manner the influences that lead to the development of premature baldness not dependent upon demonstrable disease or upon the presence of parasites, and describes the therapeutic measures to be adopted in accordance with a knowledge of the anatomy and physiology of the parts.

The fact that baldness is more common in men than in women, and that when it occurs in the latter not the same parts of the head are affected as in the former, at once suggests the thought that the source of difference is to be found in the care and covering of the hair in the two sexes. In males, baldness usually first appears over the frontal bone, centrally or laterally, or over the occipital bone just above the protuberance; while in women the hair is first prematurely lost behind the ears or at the vertex of the head.

Men, as a rule, wear heavy, rigid, impermeable hats, provided with bands that constrict the forehead, so that the normal ventilation of the skin of the scalp is interfered with, while perspiration is stimulated and evaporation prevented, and circulation and innervation are interrupted. The parts, by being kept heated and moist, are softened and rendered unhealthy; the growth of the hair is unduly stimulated, and the result is an imperfect product. Women, on the other hand, wear light, open hats that interfere little or not all with the nutritive conditions and nervous supply of the scalp. Men, too, usually have their hair cut short and are not hardened to exposure of the bare head, while in women the reverse conditions obtain. Short hairs grow faster than, but do not possess as much vitality as, long hairs, nor do they afford the scalp similar protection. When women become bald, some neglect or vice can be found similar to that which accounts for baldness in the male.

Intellectual application contributes to premature baldness only indirectly, by its usual association with neglect of proper physical exercise and regularity in the mode of life. Emotion, anxiety, grief, fright, excessive indulgence in alcohol and tobacco, and certain reflex influences may induce baldness. A powerful predisposing factor to the occurrence of premature loss of hair is heredity.

The treatment of the form of baldness here under consideration naturally suggests itself. In the first place, in a prophylactic way, the headgear is to be as light as possible; it should be provided with openings for the purpose of ventilation, to facilitate the evaporation and escape of the perspiration; by the use of a convoluted band the pressure upon the head can be graduated and distributed; and by wearing the hat back upon the head rather than down over the eyes the pressure will also be reduced to a minimum. In the summer a sun-shade should be used, but the hat should be especially light and airy. The hair should not be cut off too short. It is a common belief that frequent cutting will prevent the development of baldness; but this is a fallacy. The hair should be carefully combed and brushed.

Soap and water will rarely be required. Artificial oils rubbed in by means of the hands are to be avoided when the hair is short. The hair should, under proper circumstances, be exposed as much as possible to facilitate evaporation and to diminish the sensitiveness of the part. In the summer it is well to expose the head morning and evening to the sun.

When baldness threatens or has already set in, the hair should several times daily be systematically brushed radially in all directions from the summit. The occipito-frontal muscle should be exercised also several times in the course of the day. Frictional electricity, by means of a gutta-percha plate (with an insulated handle) rubbed upon a dry cloth or piece of soft leather, should be employed a couple of times a day. The erectores pilorum of the affected part can be stimulated by stroking the nape of the neck with a coarse bathing-glove, that may be warmed if necessary.

In case there be a suspicion of a parasitic origin, the following solution may be applied topically: R. Ethereal oil of cloves, five drops; pure water of ammonia and pure glycerin, each eighty minims; tincture of sabadilla, one ounce. The application is made once a week by means of cotton; after an interval of from fifteen minutes to half an hour the parts are washed with soap and tepid water. The hair should be methodically brushed, and the occipito-frontal muscle should be exercised three times day; frictional electricity should be employed, and the nape of the neck should be stimulated morning and evening. The following order of procedure should be adopted: Brushing, exercise of the occipito-frontal muscle, stimulation, electrization.

DR. ROBERTS BARTHOLOW.

THE members of the medical profession will be gratified to learn of the complete restoration to health of DR. ROBERTS BARTHOLOW, and of his resumption of practice in Philadelphia. We trust, and are confident, that many years of great usefulness and honor await this keen intellect, whose contributions to the science, the literature, and the art of medicine are known throughout the medical world.

We have pleasure in announcing an article upon the treatment of cholera, by DR. BARTHOLOW, which will soon appear in THE NEWS. Upon this subject probably no American physician is capable of speaking with a greater authority or from a larger personal experience.

REVIEWS.

A MANUAL OF BACTERIOLOGY. By GEORGE M. STERNBERG, M.D. Illustrated with heliotypes and chromolithographs, and 268 engravings. Pp. 886. New York: William Wood & Co., 1892.

THE last quarter of the nineteenth century will be marked in history as the period of the cultivation of two of the most profitable fields of human knowledge, and it would be difficult to decide whether the harvest of the electrician or that of the biologist is most replete with blessings to mankind. One has but to compare Dr. Sternberg's new treatise on Bacteriology with his similar publication of ten years ago, to be impressed with the wonderful advances that have been made in the knowledge of microörganisms within that time. No American is better fitted for the task of reviewing the present state of bacteriologic investigation than Dr. Sternberg. As the pioneer bacteriologist of this country, the author first attracted attention about 1879 by his investigations into the etiology of yellow fever, since which time his name has become familiar from his various publications on septicemia, pneumonia, disinfection, etc., and his position as Director of the Hoagland Laboratory of New York City. The author's practical experience has enabled him to select from the almost endless variety of technologic devices and methods which have been suggested from time to time, and to present a clear statement of such technique as is necessary to an understanding of the life-history of microörganisms.

It is to be regretted, however, that the subject of filtration is passed over in but a cursory manner, inasmuch as it is quite time that the public should be awakened to the shameful manner in which it is being deceived by venders of filters. That "the porcelain filter is the most reliable and convenient for accomplishing the object in view"—the sterilization of culture-fluids in the laboratory—is all well enough, for there its shortcomings are understood; but thousands of citizens are being led to trust these filters implicitly for the removal of disease-germs from drinking-water, and as Dr. Sternberg's book is undoubtedly intended, in part, to furnish busy practitioners of medicine with knowledge that will enable them to give good advice in bacteriologic matters, it strikes us as scarcely sufficient to pass over the imperfections of this and all other filtering devices with the remark that "after the filter has been in use for some time it may permit the passage of bacteria, and it will be necessary to subject it to a high temperature for the purpose of destroying all organic matter contained in the porous porcelain." We would here call attention to a paper read by Dr. Chas. G. Currier before the Section of Public Health of the New York Academy of Medicine, April 5, 1889, on "The Efficacy of Filters and of Other Means Employed to Purify Drinking-Water," and to recent articles in the *Centralblatt für Bakteriologie und Parasitenkunde* by Babes, Giltay, Aberson, Jolles, Smith, Moore, etc., proving beyond contradiction that filters, as commonly employed, not only do not keep back bacteria, but furnish a nidus of the most dangerous sort for their

growth. By far the most interesting chapter of Dr. Sternberg's book is that treating of Susceptibility and Immunity, and we would wish the book a wide circulation for this one discussion alone, which places the reader in touch with the practical outcome of bacteriology as related to the prevention of disease, and by which he is encouraged to hope that the study of "toxines" and "antitoxines" will eventually lead to the intelligent and successful practice of *antitoxination* for the prevention of many diseases besides anthrax and smallpox. There appears to be a most promising field of research in relation to the possibility of acquiring immunity to certain toxins through inoculation with the blood-serum of immune animals.

The systematic treatment of pathogenic and saprophytic bacteria is all that could be desired, although in connection with the consideration of bacteria in infectious diseases not proved to be due to specific microorganisms space might well have been given for a few words indicating the tendency of recent research in the etiology of these diseases, as, for example, the claims made for *Dochmius duodenalis* as the cause of beri-beri, or for the sporozoa in carcinoma, as, in fact, the author has done in speaking of malaria. As regards the bibliography, its use would have been greatly facilitated by the employment of numbered references. Dr. Sternberg is to be congratulated in having so successfully digested the enormous mass of bacteriologic literature that has accumulated during the last decade. The book is thoroughly scientific throughout. It would have seemed fairer had the author taken pains to give as great prominence to the many creditable researches of other American investigators as to his own, which are frequently referred to in the bibliography. Most of the illustrations are good, particularly the heliotypes. The chromo-lithographic work is not up to the mark, when compared with that in similar German and French works. The presswork deserves no praise, being in many places very uneven, while the index is quite inadequate.

A DICTIONARY OF PSYCHOLOGICAL MEDICINE. Edited by D. HACK TUKE, M.D., LL.D., Examiner in Mental Physiology in the University of London; Lecturer on Psychological Medicine at the Charing-Cross Hospital Medical School; Co-Editor of the "Journal of Mental Science." Two vols. Philadelphia: P. Blakiston, Son & Co., 1892.

THIS work is destined to rank among the medical classics, and will add luster to the reputation that has already been achieved by its distinguished editor. It is not the product of hasty, spasmodic efforts, but shows throughout the results of careful garnering, scholarly method, and editorial judgment as to both matter and style. It contains more than the title, *Psychological Medicine*, would lead one to expect; many related subjects are treated, but none of which the physician and the student of psychiatry should not have knowledge. It is practical in the highest sense; a book that will become a standard work of reference for the general practitioner of medicine, as well as for the neurologist and the alienist. It is an improvement upon many of the latter-day dictionaries and encyclopedias, medical and otherwise, in the careful allotment of space to subjects, and in the editorial revision of language. Dr. Tuke has chosen his contributors not only from Great Britain, but from the workers and writers of continental Europe, and to a limited extent from our own country. American names that would naturally be looked for are not to be found in the list of contributors, which, however, includes such distinguished authorities as Chapin, Cowles, Donaldson, Earle, Jastrow, and Lombard.

Such a work is worthy of analysis and review, and of careful discussion and criticism of special articles, but the space assigned to a brief notice will not allow of this. The editor is not only an editor in fact, as well as in name, but has contributed between sixty and seventy of the definitions and articles, including such important and diverse subjects as Historical Sketches, Bedsores of the Insane, Classification of Insanity, Constipation in the Insane, Ecstasy, Mental Disorder following Influenza, The Sibyls, Somnambulism, Statistics of Insanity, The Insane in Turkey and Egypt, Vampirism, etc. Old-fashioned, and sometimes perhaps unprofitable, erudition is shown in many of the definitions. Many doctors, not excluding some neurologists and alienists, may learn here for the first time that *anhaphia* means diminution or loss of tactile sensation; that *cenospudia* is brown study, and that *oligopyschia* is imbecility or fatuity, a word which, with the editor, we will agree is quite unnecessary. Not a few terms have been introduced which are of little or no practical value, but are occasionally met in the literature of psychology and psychiatry, and therefore very properly have been defined.

It is difficult, without being invidious, where so much is meritorious, to choose for special mention particular contributions, but we might speak of the article by Ritti on Circular Insanity; of that on Consciousness, by Mercier; of that on Criminal Responsibility, by Orange; and of the medico-legal articles and definitions in general, which will prove of value to the legal as well as to the medical profession. Mickle writes of General Paralysis; Clouston, of Developmental Insanities; Langdon Downs, of Idiocy; Horsley, of Cretinism and Trephining; Charcot and Donkin, of Hysteria. Chapin contributes the article on Provision for the Insane in the United States, and Urquhart a Chronological Bibliography, beginning with 1584 and ending with 1892. Editor, contributors, and publishers are all to be praised.

DISEASES OF THE CHEST, THROAT, AND NASAL CAVITIES, including Physical Diagnosis and Diseases of the Lungs, Heart, and Aorta, Laryngology and Diseases of the Pharynx, Larynx, Nose, Thyroid Gland, and Esophagus. By E. FLETCHER INGALS, A.M., M.D., Professor of Laryngology and Practice of Medicine, Rush Medical College; Professor of Diseases of the Throat and Chest, Northwestern University Woman's Medical School; Professor of Laryngology and Rhinology, Chicago Polyclinic, etc. Second edition, revised and enlarged. 240 illustrations. 8vo., pp. 700. New York: William Wood & Co., 1892.

THIS concise and reliable manual well deserves a second edition. Its author is an experienced practitioner, whose specialism rests upon the broad foundations of general medicine, and he is therefore cautious not to lead students astray by laying undue stress upon

local accidents and coincidences. While, in some instances, we might have desired a different allotment of space to the various topics, this is, after all, a matter of personal judgment, and the author has evidently omitted or condensed with reason, and not at random. While he spells hemorrhage without the diphthong, yet the old and cumbrous form is followed in "anæsthesia," "œdema," "œsophagus," etc. The practice in any book should at least be uniform, and THE MEDICAL NEWS believes that it should be modern. While making due allowance for individual judgment, the section on Diseases of the Lungs and Heart cannot be considered complete when all reference to the important subject of pneumotherapy is omitted. The little said about Exophthalmic Goiter is likely to be misleading.

NEWS ITEMS.

Prize Essay on Homeopathy.—Thirteen essays in competition for the prize of One Hundred Dollars offered by Dr. George M. Gould (see THE MEDICAL NEWS, May 7, 1892, p. 510) have been received, and have been read by the judges, Prof. S. Solis-Cohen, Prof. A. P. Brubaker, and Dr. George M. Gould. Without knowledge of the opinion of the others, each judge wrote his own opinion, naming the essay he considered best, and (in case of loss or other accident) also that considered the second best. Upon comparing the three judgments it was found that they were identical. The essay, signed *Iconoclast* was deemed the best, and that with the signature *Jabeni* was the second choice. This unanimity of independent opinion, where there were so many essays of a very high order of merit, is a gratifying fact. Upon breaking the seal of the envelope of *Iconoclast*, we find the card of DR. WILLIAM W. BROWNING, 155 Reid Ave., Brooklyn, N. Y., to whom the prize has been sent. The other essays will be returned to the authors when their addresses and instructions are forwarded.

Courses in Bacteriology.—In view of the possible advent of cholera during the coming summer and the great importance of biologic examinations in the diagnosis, the Directors of the Carnegie Laboratory have arranged for short courses on this subject, under the direction of Dr. Edward K. Dunham, to be open to representatives of Health Boards, Health Officers, and to properly accredited medical men. It is designed that these courses shall have the same general scope and fulfil the same purpose as the cholera courses given at the Hygienic Institute in Berlin.

It is extremely desirable that there should be medical men throughout the country who are trained in the biologic diagnosis of epidemic cholera; so that if doubtful cases appear in any locality there may be at hand men competent to at once make satisfactory biologic examinations. The first cases of Asiatic cholera in the beginning of an epidemic are always doubtful cases; and it is only by means of biologic examinations that a definite conclusion can be reached as to their nature.

The courses begin about the 20th of January, 1893. Each course will continue for about two weeks. The fee, to cover expenses incurred, will be $25.00. Applications for admission to the courses should be made in advance to the Directors of the Carnegie Laboratory.

The Milwaukee Medical Journal is a new monthly publication, under the editorial care of Dr. W. H. Earles and Dr. W. H. Neilson. The first number bears date of January, and presents an attractive appearance.

BOOKS AND PAMPHLETS RECEIVED.

Mechanical Support in Fracture and Dislocation of the Sixth Cervical Vertebra. By H. Augustus Wilson, M.D. Reprint, 1892.

Report of a Case of Talipes Equino-varus. By B. Merrill Ricketts, Ph.B., M.D. Reprint, 1892.

ORIGINAL ARTICLES.

SOME EXPERIMENTS WITH MODIFIED TUBERCULIN.[1]

BY JOSEPH EICHBERG, M.D.,
PROFESSOR OF PHYSIOLOGY IN THE MIAMI MEDICAL COLLEGE, CINCINNATI.

THE lamentable failure of the original Koch treatment of tuberculosis is still fresh in the medical mind. Heralded in advance by the one man who had inseparably identified his name with the great scourge of the temperate zone, the treatment was received with confident faith by the entire profession. The circumstances preceding, and the manner of, its publicity savored somewhat of charlatanism; but these were explained and excused on the plea that great political and personal pressure had been brought to bear on the illustrious scientist, to whom modern pathology owes so much. More than any other had he contributed to the establishment and proof of the bacterial theory in pathology as applied to every single member of the group of infectious diseases. It was but natural that to him the world of scientific medicine should turn for some practical result of his great philosophic and experimental work.

Nor was he wholly blameworthy. Clinicians of great repute and deserved eminence had closely followed his experiments, to which they lent their countenance, which they copied in detail, and subsequently reported in terms of fulsome praise, with some of their marvellous results. Few in the profession would question any statements emanating from such men as Koch, Bergmann, Gerhardt, and Senator; everyone was excited, and there went up a feverish cry, "To Berlin."

The disillusion came speedily enough. There could be no doubt of the wondrous effects of the new remedy, but their duration was brief, and following the temporary improvement there came a period of increased destruction, with dangerous complications, and not a few fatalities. Where there had been great authority to sanction, there now came the menacing voice of Virchow, commanding a halt, fully justifying, on the post-mortem table, his scathing condemnation of the method, and of its disastrous consequences.

The rocket had soared high, and its flight was hopefully followed by many a poor sufferer; the thud with which it speedily fell carried a corresponding gloom, and seemed to close another avenue of escape to many tuberculous patients, to whom there had come a promise of new life.

However, not all were willing to wholly abandon a method that seemed to rest on so secure and scientific a basis. The whole theory of establishing immunity by inoculation with attenuated cultures, a theory positively proved by Pasteur, seemed to point to some such logical result as Koch had presumably achieved. True it was, that in one case we were dealing with a healthy organism, and the inoculations were preventive; in the other, the disease was more or less fully established, and the inoculation was to be curative. In the one case we were anticipating the possible development of an infectious disease; in the other, we had to deal with an individual already in the grasp of the destroying malady.

Yet there existed between the two classes an analogy of causation so close as to reasonably suggest that a similar course of treatment would be attended with results positively beneficial. That such a line of reasoning embodies no sophistry has only lately been proved by the brilliant results of Cattani, Tizzoni, and others in the cure of fully established cases of tetanus. By inoculation with an antitoxin obtained indirectly from pure cultures of the tetanus-bacillus, no less than six cases have been reported as cured, a result far beyond the limits of mere accidental recovery.

Consequently, there came to the minds of many a certain doubt as to the expediency of wholly dropping both Koch's plan and his remedy, although the latter was then strongly in disgrace. Efforts were made by a number of observers, as also by Koch himself, to separate from so-called tuberculin those principles that gave rise to the high fever, general malaise, and increased destruction around the tuberculous deposits. If this could be achieved, the remainder might then be counted upon to manifest all of the beneficial and curative properties of the original lymph, without exposing the patient to any risk from the treatment.

In two instances have these efforts at modifying the lymph been notably successful: in the case of Klebs, who obtained from Koch's tuberculin a compound which he calls tuberculocidin, and for

[1] Read at the meeting of the Mississippi Valley Medical Association, October 14, 1892.

which he claimed great curative powers; and in the case of Hunter,[1] who made a most careful chemical analysis of the lymph, and who succeeded in isolating from the lymph a number of substances, which he designated by letter as modifications A, B, CB, etc.

The employment of modification B seemed to be attended with fewer unpleasant consequences than that of any of the others, an experience that was subsequently verified in the human subject. This modification consists in the isolation of an albumose or group of albumoses, which are re-dissolved, and then employed in a diluted form. Klebs retained the secret of the manufacture of his tuberculocidin, though he allowed it to be sold in the open market. Hunter, guided by a finer, more unselfish professional instinct, at once published his results, and also the method of preparing his modification. It is his preparation B which has been used in our experiments, the same that received the indorsement of Dr. Kinnicutt,[2] whose moderately satisfactory results, together with my own belief that we had not yet exhausted all there was in tuberculin, induced me to subject it to a test, whose results I will give in summary.

First, in defence of these experiments, which might otherwise be open to censure, it must be premised that both Hunter's and Kinnicutt's experience seemed to establish the comparative harmlessness of this peculiar agent. Without such assurance I should not have been tempted to its trial. The mere fact that want and misfortune compel many to seek the asylum of a hospital certainly confers no right upon the physician to trifle with remedies that may possibly aggravate their disorders; and it was solely because of the prominence given to the quality of the remedy, and the freedom from general and local sequelæ of an unfavorable kind, that it was given so thorough a test.

These, then, were the conditions upon which we engaged in these experiments: (1) That the injections should not give rise to any immediate local reaction; (2) that there should not follow fever, or depression, or general lassitude; (3) that there should be no symptoms indicating an increase of destructive process, or a development of fresh inflammatory change in the seat of tuberculous disease; (4) that the dosage should be regulated by careful and repeated observation of the temperature and pulse.

All these indications have been fully met. I can here give only a short *résumé* of the results achieved. Such as they are, they are full of encouragement, and mark the remedy as worthy of more extended trial.

It must be remembered that we were dealing, in the main, with a most unfavorable class of cases, that our experiments were made during an exceptionally hot summer, and that our patients were not selected with any view as to special fitness for the experiment. All alike received the injections; many were then hopelessly sick, two almost moribund; manifestly little could be hoped for from any treatment at this stage; yet it was desirable to define as nearly as possible the limits within which benefit might be derived, and this could only be done in the way suggested.

Incipient cases, those most likely to be permanently relieved, rarely present themselves for hospital aid during the pleasant weather. Still able to go about, they find some means of eking out an existence until the rigors of winter and increasing helplessness drive them to some charitable institution.

Another feature, connected solely with hospital life, has had its bearing upon our cases. The hospital authorities have no power of imposing restraint upon any patient, except in the cases of such as are under police surveillance. As soon as a patient insists upon his discharge, it must be granted, even though it be against his own interests; and, in most instances, it is useless to appeal either to his reason or to his fears. Thus it happens that some of our most promising cases passed beyond control after the first manifest improvement in their condition had taken place. In private practice, mere self-interest will bind the patient in such a case, so long as there is any hope of further betterment.

The injections were made daily by means of a syringe with asbestos wrapping and packing. The syringe and needles, as also the glass cups for the solution, were sterilized daily before using—a precaution which I believe unnecessary, but which was followed throughout, to avoid any accidental contamination. The solution was kindly prepared for me by Mr. Mark Brown, of Miami Medical College, in the laboratory of the Cincinnati University, according to the directions given by Dr. Kinnicutt.[1] The lymph, from which the solutions were made, was part of an unbroken package, received from Germany about two years ago. In the process of preparation all apparatus was sterilized, and the water used in dialyzing was previously boiled. The

[1] Method of preparation of Hunter's modifications. Modification B: 1 c.c. of tuberculin, 5 c.c. distilled water, saturation with preferably large crystals of ammonium sulphate for twenty-four hours in the cold, the precipitate filtered off and freed as far as possible from any crystals of ammonium sulphate, placed in the dialyzer, and dialyzed just so long and no longer in running water, and then in distilled water until all trace of ammonium sulphate has disappeared. Crystals of thymol are added to the solution to prevent any putrefactive change: the solution is then made up to such bulk that 10 c.c. shall correspond to each c.c. of tuberculin employed. (Title: B, 10 per cent.)

dialyzer consisted of fine sausage-casing. The solution was received and kept in sterilized glass-stoppered bottles.

In a kind letter from Dr. Kinnicutt, he says: "Both Dr. Trudeau and I deemed it prudent to still further dilute the 10 per cent. preparation B and CB. The formula which we adopted was as follows: 1 c.c. of the 10 per cent. solution was diluted with 10 c.c. of ½ per cent. carbolic acid solution, and of this 0.002 gram was used by me for the initial inoculation; 0.005 gram by Trudeau. By me the dosage was increased by 0.002 gram daily, by Trudeau by 0.005 gram. If any elevation of temperature above 100° F. followed an inoculation in an apyretic case, the same dosage was retained until such a rise ceased to be developed. In pyretic cases the daily range without inoculation was carefully studied for several days, and any rise above the daily range, following an inoculation, was regarded as an indication to diminish the dosage or hold it at the same amount. As I stated in my lecture, the B preparation only should, in my judgment, be used."

These directions have been carefully followed, except that the increase of dosage, begun at 0.0025 gram, was afterward changed to 0.005 gram daily in cases in which tolerance was well established. In no case did the amount injected exceed 0.100, which, as we were dealing with a 1 per cent. solution of the original lymph, represents a very minute dosage. In some later experiments reported by Trudeau,[1] the initial dose was 0.003 gram daily, which was finally carried to 0 7 or 0.8, the increase being slowly kept up as long as no rise of temperature occurred; but there seemed to be no indication in our cases for any larger dose than the one mentioned. Indeed, symptoms of decided improvement set in in a considerable number of cases before the dose reached 0.03 gram of the diluted solution.

The clinical material embraces twenty-nine cases of undoubted pulmonary tuberculosis, one of lupus, and one of tuberculous peritonitis. With reference to the latter, some doubt may be expressed as to the accuracy of the diagnosis. The only reply that I can make is that all of the symptoms ordinarily manifested in tuberculous peritonitis were present; that there was at the same time incipient pulmonary tuberculosis, with continued fever; and that the patient was a negro, chronic tuberculous processes being especially common in the colored race. In this case perfect recovery ensued.

The case of lupus, which had been treated a year before with the original tuberculin without success, remained under observation for too short a time to furnish any reliable data, the patient being expelled from the hospital for insubordination. Another patient, a case of pulmonary tuberculosis, with beginning excavation of the lung, improved so much that he felt obliged to celebrate the change in his condition by assaulting the cook, whom he thoroughly worsted in a fistic encounter; though, at the time of his admission, this patient was unable to leave his bed. One case of pulmonary tuberculosis, with elastic fibers in the sputum, was discharged perfectly well; fever, cough, expectoration, all had disappeared, and there was a gain in weight of fifteen pounds.

Of the 29 cases of pulmonary tuberculosis, 22 were males, 7 females; 4 of the latter were colored. The ages of the patients ranged from twenty-one to fifty-one years, 11 being below thirty, and 9 below forty years of age. Six patients died; one had, in addition to the pulmonary changes, chronic interstitial nephritis; one died twelve days after admission from a complicated tuberculous laryngitis, which rendered swallowing very difficult; another had total adhesion of the pericardium, with fatty kidneys; a fourth was almost moribund on admission, but lived seventeen days.

In no single instance could it be said that death was hastened by the injections; nor, in the case of tuberculous laryngitis was there any change for the worse in the local ulceration. In no case was hemorrhage observed to follow the injections. In general, all patients, without exception, declared that they felt better, breathed with greater freedom; a weight seemed to be lifted from the chest, and the general condition seemed to indicate a better tone.

Of the remaining cases, three are still in the hospital; one was discharged at her own request in a condition little better than when she came; one was discharged well; one nearly well, and fourteen were greatly improved.

A rating as to improvement was based upon a gain in weight, a diminution in the frequency and severity of cough, diminished quantity of expectoration, and cessation of night-sweats. The physical signs were altered, inasmuch as dry sounds took the place of coarse, moist râles and fine crepitations, showing clearly an arrest of the destructive changes in the lung-tissues. The computation of the bacilli was not made, owing to the uncertainty attending such estimates.

The average stay in the hospital of all cases subjected to the treatment by inoculation was 56.6 days. Few cases received inoculations for more than fifty days, many leaving earlier—as soon as they had in a measure regained their strength. In no instance did a patient suffer any local inconvenience about the point of inoculation. For the

[1] THE MEDICAL NEWS, September 10, 1892, p. 299; September 24, 1892, p. 364.

most part, the injections were given in the infraclavicular region; for no other reason than that the parts, being already exposed by the examination, offered a convenient surface. The strength of the solution was gradually increased, so that the amount given never exceeded the contents of one syringe.

The effect on the urine was, in many instances, decided; an increased flow rapidly followed the inoculations, and the daily average remained higher during the time of the experiments. The first effect on the sputum was to cause an increased expectoration, to be followed later on by a gradual diminution. Parallel with this was a change in color and composition, the sputum becoming less viscid and more distinctly mucous in character. The cough became less troublesome. Three of the cases were interrupted in their convalescence by a prostrating diarrhea, which seemed in no way connected with the inoculations.

The most surprising effect was observed in the temperature. By the exercise of great industry the nurses in the respective wards kept records for two weeks of hourly observations of the temperature before and after the injections. Subsequently, these were supplemented by records taken every three hours.

In but the fewest instances was there noted any decided rise, *i. e.*, to, say, more than 2°; while in the larger number there was, within the six hours immediately following the injection, a decline of between 2° and 3.5°; this decline followed whether the injections were made early or late in the day, so that it was not due to diurnal variation. In cases in which originally there had been continuous fever, it was noted that in all, save the most advanced, the mean daily temperature steadily declined, approximating the normal line during the entire twenty-four hours. In cases that were apyretic at the outset the thermal line remained subnormal during the greater part of the twenty-four hours.

The experiments were sometimes interrupted for a day or two, when it was noted that the maximum of the intervening days was higher than when the injections had been given. It was a common experience to find the temperature after midnight subnormal. The pulse-rate was slowed, but without much gain in the volume or force of the circulation. In apyretic cases there was never any increase of temperature.

In conjunction with the inoculations all patients received five-drop doses of creasote, with oil.

Our present position has been well expressed by Trudeau in the paper already quoted. "More extended research and clearer knowledge of the various elements, both beneficial and injurious, contained in bacterial products, as well as of their effects upon tuberculous animals, may in the future lead to still further improvement in this as yet tentative method of treatment. At present its limitation to early and apyretic cases seems indicated." On the strength of our own experience we would go somewhat further. The greatest benefit—indeed, complete restoration with cicatrization of tuberculous deposits—may be hoped for in incipient cases during the apyretic stage; but even in advanced cases some improvement, with consequent prolongation of life, will be frequently observed. Experiments hitherto reported have, in the main, been carried on in localities in which the altitude and climate contribute greatly to favor a cure. Yet the fewest of patients will be so situated financially as to avail themselves of climatic changes; indeed, the majority will not be able to do so. It is especially with a view to again call attention to the possibilities of prompt treatment in the incipient stage of such cases that I have reported this comparatively limited number of observations.

THE TREATMENT OF TUBERCULOUS LARYNGITIS WITH MODIFIED TUBERCULIN.[1]

A Preliminary Report.

By MAX THORNER, M.D.,
of Cincinnati, Ohio.

Not more than twelve years ago tuberculosis of the larynx was considered an incurable disease—so hopelessly incurable, in fact, that nobody attempted to treat the local affection with the view of healing it, but simply for the purpose of alleviating, if possible, the agonizing sufferings of the patients. It was in the year 1880 that Prof. Moritz Schmidt, of Frankfurt, reported sixteen cases of tuberculous laryngitis that he had cured (of which number, after thirteen years, there had been no recurrence in the larynx in two).[2] Then, for the first time, it was strikingly emphasized that one should enter upon the treatment of laryngeal tuberculosis with the view of a possible cure, and subsequent events have proved the correctness of this position. I need only mention the names of Heryng, of Warsaw, and Krause, of Berlin, who, by their surgical treatment of this affection, have established the fact (as many others, too numerous to mention, have also done by other methods of treatment) that there is a possibility of laryngeal tuberculosis being cured. Unfortunately, the number of such cases cured and remaining so is exceedingly small.

It is, therefore, not to be wondered at that, when the first enthusiasm over Koch's tuberculin had subsided, the disappointment was so much the greater. The agent had not done for the larynx

[1] Read before the Mississippi Valley Medical Association, October 14, 1892.

[2] M. Schmidt: Tuberculin bei Kehlkopftuberculose. Verhandl. d. X. Cong. f. inn. Medicin. Wiesbaden, 1891.

what had been expected; for the larynx was the very region to demonstrate *ad oculos* the curative action—to allow the study of every phase of any change that might take place. It was in this sense that Lennox Browne wrote in his early monograph on Tuberculin: "*Not only is the larynx the most appropriate place for the study of true tubercle, but it is also the most appropriate and convenient site for accurate observation of the various stages of its development toward reparation which takes place under Koch's treatment.*"[1] The outcome of the numerous experiments is yet fresh in our minds. Referring to the larynx alone, the cases in which improvement or cure followed the administration of the lymph were few, while evil results followed in many cases. Not only did new tuberculous eruptions occur in situations in which previously the tissues appeared healthy, but swellings and edema developed in many cases, causing threatening dyspnea, which, in a few cases, necessitated tracheotomy.

When "crude tuberculin" (as it was afterward called) had fallen into disuse, there were quite many observers who were at heart convinced that the underlying principle of the treatment was correct, and that it would finally be triumphant. This idea is very prettily expressed by Prof. M. Schmidt in his concluding remarks on "Tuberculin in Laryngeal Phthisis," when he says:[2] "If this experiment should fail, we shall be compelled to bid farewell for some time to the light that shed so brightly its warm rays of hope into the most profound depths of human misery. The road, however, opened to us by the great Robert Koch is sure to lead us some day to our goal."

Since that time experiments have been made with some modifications of tuberculin, the details of which have already been entered into. The following two cases have been treated with Hunter's modification B of tuberculin,[3] for the supply of which I am indebted to Dr. Joseph Eichberg, who has also seen the cases several times with me. The injections were always made between the shoulder-blades, with carefully sterilized syringes and needles. The temperature was taken every two hours, from 7 A.M. to 9 P.M., the patient always sleeping soundly through the night.

CASE I.—Charles V., forty-three years old, was first seen March 24, 1892. He had been discharged from St. Mary's Hospital but a few weeks previously, where he had been under treatment for pulmonary tuberculosis. At the time of his discharge from the hospital the cough had improved. At the time of his first visit he was coughing incessantly, was very hoarse, complained of pain in the laryngeal region, and had some dyspnea. He was a typical case of pulmonary tuberculosis. He weighed 123 pounds. His temperature ranged from 98.4° to 101.6° F. Physical examination revealed the presence of an active process in the lungs. Tubercle-bacilli were found in the sputum.

The entire larynx was congested; the left vocal band was intensely swollen to double its normal size, especially so in its posterior portion; the upper surface and free edge were rough and uneven, having the appearance of being covered with small excrescences, which assumed a bunch-like shape near the inter-arytenoid fold. The processus vocalis was marked by a small yellowish ulcer; beginning at this particular spot there was considerable swelling, confined to the laryngeal side of the mucosa covering the left arytenoid cartilage; this infiltration was also the seat of several superficial ulcers; the lower surface of the left band was considerably infiltrated, presenting the appearances seen in an attack of chorditis vocalis inferiorjs acuta; while repeated examination, with the aid of Prof. Killian's excellent method,[1] failed to disclose any affection of the posterior laryngeal wall, a favorable location for tuberculous deposits.

Surgical treatment being contra-indicated on account of the extremely weak condition of the patient, the larynx was treated locally with lactic acid and menthol. Internally the man took beechwood creasote. This treatment seemed to hold further advance of the local trouble in check, whilst the general condition had improved materially at the time when the injections were begun. He had gained ten pounds; felt stronger; coughed very little, at times not at all. There was not quite so much hyperemia of the larynx, and some of the small superficial ulcers had healed. Otherwise the condition was unchanged. The temperature ranged from 98.6° to 99.4° F.

On September 5, 1892, the first injection of 0.0025 of tuberculin was practised. This amount was gradually increased until, on October 8th, 0.1 was reached. The injections were made every day. The temperature ranged from 98° to 99.6°. Only on one day was there a temperature of 100.2°, and this was the second day after I had commenced injecting 0.1; after that the temperature returned to 99.6°. The highest temperature was usually found from two to four hours after the injections, which were generally made between 10 and 11 A.M. The lowest temperatures were registered in the early forenoon. Ordinarily, the temperature did not rise above 99°. The general condition of the patient was always good. Only during the first few days did he complain of general malaise, sometimes of headache; but these soon left him, never to return.

The laryngoscope at no time revealed any increase of the hyperemia, any new swelling, any evidence of tuberculosis in places previously free.

[1] G. Killian: Die Untersuchung d. hint. Larynxwand. Jena, 1890. Rudolf Keller: Zur Tuberculose der hint. Larynxwand. Inaug. Dissertation, Freiberg, 1892.

There was, in fact, at no time any untoward symptom noticed in connection with the larynx. After the fifth injection it was possible to notice a subsidence in the congestion. The congested mucosa gradually assumed a paler color, while the infiltration of the vocal band, especially in its anterior portion, had greatly diminished at the end of the third week, when Dr. Eichberg saw the case again; the large superficial ulcers over the arytenoid had healed, and the lobular swellings around the processus vocalis had decreased in size; the subglottic swelling had also greatly abated. This improvement continued, though slowly, but in an unmistakable manner. On October 6th, one month after the first injection, the patient volunteered the statement that he experienced much less dyspnea when walking up hill. On October 14th, the improvement had continued; there remained only a small portion of the excrescences in the posterior part of the cord; the subglottic swelling, though still visible, was materially reduced, and the mobility of the left cord was greater. The voice was clearer than before.

CASE II.—Mrs. S. M. H., thirty-five years old, has had pulmonary tuberculosis for a number of years, an exacerbation usually taking place in the autumn. For two months she had complained of pain in swallowing. Tubercle-bacilli were found in the sputum.

On September 20, 1892, laryngoscopic examination showed the epiglottis to be considerably thickened; on the laryngeal surface, near the left upper border, was a yellow ulcer as large as a split-pea. There was also considerable pear-shaped swelling of both arytenoids, and some slight swelling of the inter-arytenoid membrane. The temperature ranged between 98.8° and 99.8° F. On September 27th, a first injection of 0.0025 was practised. The dose was gradually increased every day until it was 0.035. There was never any untoward symptom in connection with the larynx. The small ulcer healed; the infiltration of the epiglottis slightly diminished; otherwise the condition remained unchanged. The temperature ranged from 98.6° to 99.6°. The patient became able to swallow without pain.

These two cases are insufficient, and the time of observation is yet too limited to permit of any definite conclusions. They seem, however, to encourage further research in the same direction with some of the modifications of tuberculin. I shall certainly continue to investigate the effect of this powerful preparation, deprived of its toxic constituents, and I confidently hope that many others will do the same, for, as the late S. D. Gross has said: "In an inquiry of this kind individual experience amounts to nothing; collective experience is everything."

Adolph Baginsky has been elected Professor of Pediatrics at the University of Berlin.

SOME PERSONAL OBSERVATIONS AND REFLECTIONS UPON ALCOHOLISM, THE EFFECTS OF ALCOHOLIC ABUSE UPON POSTERITY, AND THE TREATMENT OF ALCOHOLISM.[1]

BY H. ERNEST SCHMID,
OF WHITE PLAINS, N. Y.

I DO not know of any subject which is of greater importance than alcoholism to the individual, the family, and even to the nation at large. Alcoholism far exceeds in interest, magnitude, and wide-reaching consequences, morphinism or any allied vices. He who lives under the constant influence of an opiate will become conspicuously obnoxious to those surrounding him only when deprived of the enslaving drug. In the majority of instances he will commit acts of selfishness and cruelty only when impelled by the bitterest misery to secure, at any hazard, the means of purchasing more opium or cocaine, or whatever special form of anodyne or opiate to which he may be particularly attached.

According to my, not small, experience, when supplied sufficiently with all he craves, beyond being a social nuisance, he is comparatively harmless. But how different with the man who drinks to excess! In many instances he becomes a brute, and acts brutally toward strangers, friends, and relatives.

In order to criticise, or select intelligently, a plan of treatment adequate to the greatness of the subject, it is but proper to contemplate first the way in which alcohol damages the system. Of course, I speak of the damage wrought by its abuse.

The effectively intoxicating part of all alcoholic beverages is called ethyl-alcohol, and by pharmacologists is properly ranked with the poisons; but, in common with other drugs of the same class, it is, in suitable cases, prescribed by physicians, for when a physician orders brandy in the form of cognac, his patient thus takes about 55 per cent. of ethyl-alcohol. When he orders Malaga wine (a favorite prescription for children in certain countries), the little one gets from 17 to 28 per cent. of the same alcohol, and in lager beer 3 per cent. to 5 per ecnt.

It has often amused and astonished me at the same time when I have heard it said that lager beer is a non-intoxicating drink, as, for example, the man who imbibes ten glasses of it (often but an ordinary feat) drinks about half a glass of pure ethyl-alcohol. This substance is carried into the blood, chiefly through the intestinal veins, and to some extent through the chyle-vessels. It speedily passes through the walls of the vessels, and the richer an organ is in blood the more of the alcohol it imbibes. The rapidity with which the entrance of alcohol into

---

[1] Read at the meeting of the New York State Medical Association, held in New York, November 15, 16, 17, 1892.

the system is effected is truly astonishing, for in only a few minutes after it is swallowed it can be found in the venous and arterial blood and in the main trunk of the lymph-vessel system.

Of all the organs that absorb this poison from the blood the brain is the first in this process, and hence also first in showing its effects. It is thought that the action upon the nerve-centers is atomic or molecular in character. If the excess in drinking is slight, and of short duration, this atomic union will occur in a very loose manner, so that the alcohol must soon let go its hold again, so to speak; but when severe and protracted indulgences are practised the chemical affinities of the nerve elements are paralyzed, and their life finally destroyed.

Next in order comes the heart, whose action is quickened, resulting in a more rapid pulse, while the tension of the arterial walls and blood-pressure are lessened. The blood itself is *not* changed by the alcohol.

Upon the digestive function alcohol exerts a peculiar influence. Small doses, diluted, stimulate and increase the secretion of the gastric juice; whereas, large amounts interrupt, delay, or entirely suspend it. Competent observers maintain that any quantity at all, if taken during the process of digestion, produces the latter effect.

Tissue-change is decreased, according to almost all observers, by the use of alcohol. The breathing, at first accelerated, gradually becomes slow, and the excretion of carbonic acid is lessened. The temperature of the body is affected only by large doses, which lower it. A great expenditure of warmth is caused by the dilatation of the vessels of the skin, by paralysis of the muscles, and by a reduction of the oxidizing processes in the tissues.

A study of the intoxicating and, hence, destructive effects of alcohol upon a child, gives still more guidance to its proper treatment in the adult alcoholist. There we notice far more clearly how powerfully the nervous system is attacked by it. The first stage is almost always one of excitation, though this is occasionally absent in the child, as well as in the adult, either on account of a large quantity, or a very susceptible organism. This stage of excitation is marked by a great sensitiveness to external excitants, and by most active muscular unrest, often progressing to light muscular spasms of a clonic or general tetanic character. In the next stage the child becomes deeply depressed. There is a relaxation of nerves and muscles, resembling paralysis. In this condition, coma-like, it may lie from twelve to thirty-six hours, being roused with difficulty, and only for moments at a time.

Occasionally, I have said, there is an absence of the first period of excitement, and the rapidity of the absorption of alcohol is exemplified by an action almost lightning-like upon the central nervous system. I once saw a man drink a full goblet of whiskey, and in less than five minutes, a second. A third was attempted, when all at once the glass fell from his hands, and he lay senseless upon the floor. He was ill for weeks.

During the first week of September I was called to see two cases of alcoholism that were to be treated at the Keeley Institute. Both, however, arrived in so terrible a condition that I was sent for to see if they could be roused from the almost coma-like state in which the last drink had placed them. It was impossible. One expired within fifteen minutes of the time I first saw him, the other within two hours. The latter presented a very interesting point. He was pulseless, unconscious, insensitive to any touch; his feet and hands were cold. I gave him hypodermatic injections of brandy, and he reacted. In an hour he was perfectly conscious, answering all questions, but he lived only about two hours from the time I made my first visit. I mention these cases on account of the interesting deductions to be made from them.

In prescribing alcohol for a child we should always bear in mind that it not infrequently produces convulsions in the infant; and, furthermore, that even very small doses of it act only transiently as a vivifier and apparent strengthener of the nervous system; even then, such effects are soon followed by relaxation. In reality alcohol only transiently benumbs the feelings of weariness; and finally, in larger doses it produces a momentary, never an enduring strength. It is, therefore, indicated medicinally only in that pathologic condition that approaches collapse, with a frequent and small pulse. In such cases alcohol may serve to "tide over," by causing temporarily a slower, fuller, and stronger pulse.

We should also never forget that in tea and coffee we have the agents, *par excellence*, that raise and sustain strength in muscular and mental labor, and this is truer of tea than of coffee. The wife of Lieutenant Peary, lately returned from a most successful North-Pole expedition, informed me that tea almost always, coffee rarely, was their beverage.

Alcohol was some time ago excluded from the quartermaster's department of Northern expeditions. It is a mistake on the part of any practitioner to direct even the smallest doses, long continued, of alcohol in water or milk, to be given with a view of imparting strength. This it will not do, but will disturb the natural course of digestion by inducing chronic irritation of the mucous membrane of the stomach, with dyspepsia. Chronic gastric catarrh, difficult of correction, enlargement of the intestinal lymphatics, rapid loss of weight and strength, and

in a few instances cirrhosis of the liver, are some of the pathologic conditions that follow long-continued use of even small doses of alcohol.

But what are these effects compared with those wrought upon the central nervous system of the child? The answer can occasion no surprise if we recall the grave and constant anatomic lesions that develop in the cerebro-spinal system of the adult alcoholist.

The delicate nerve elements of the child are still in an active state of development, *i. e.*, more full of blood than later in life, and the meninges therefore very prone to congestions, to dangerous serous effusions and to inflammations. For these reasons alcohol must affect the brain of the child much more injuriously. From its baneful influence often arise epilepsy and chorea. That, in many cases, alcohol is the cause is recorded by thoughtful and investigating physicians, and has been proved by the happy cure of these dreadful nervous disorders as soon as its use was discontinued.

I cannot resist alluding with a deeply-felt word of warning to the pernicious practice of allowing and even prescribing for nursing women the systematic use of alcoholic drinks with a view of producing a greater flow of milk for the baby; it is often advised by the family physician, and the hired wet-nurse stipulates as her right a certain daily allowance of beer or whiskey in the shape of milk-punch.

Could a sadder mistake be made? These same men, who allow or advise the practice, are doubtless opposed to the use of so-called swill-milk, which means milk from cows fed on distillery grain, by the eating of which they are kept in a chronic state of mild intoxication. But opposed as they are to the employment of swill-milk for adult or child, they help to produce in the human female a similar swill-milk for the poor infant. Competent and close observers have discovered a connection between this habit of the mother and the development in the children afterwards of true imbecility, and even idiocy.

Of all the effects upon the nervous system of the child, however, the most distressing and far-reaching is that upon the moral power, upon the morality of the being. Alcohol paralyzes this. The youth, who, so to speak, was alcoholized as a child, gives free reign to his passions. His will-power stands at zero. Dissipations have no terror for him at the very first meeting of them, nor have crimes. He not infrequently ends his career as a suicide.

Neurasthenia is a growing evil, even amongst the school children. Think how one admires, almost as a curiosity, a really fresh, sound, healthy child. As head of our local Board of Education for many years, I have given more than usual attention to the young in my district, and I have been astonished to find how many pupils at the age of from twelve to fifteen complain of headache, palpitation of the heart, insomnia and bad feelings generally—or perhaps they are dull and indifferent to everything, and display great weakness of memory and unnatural sleepiness and easily-induced exhaustion. Parents of such unfortunate and uninteresting and non-progressive children are very likely to ascribe all the shortcomings of their poor children to the fault of the much-suffering teacher.

What must be the effect of all such changes if allowed, unchecked or unremedied, to go on into adolescence and manhood? I think far beyond the wretchedness with which it burdens the entire life of such an adult is to be considered the inheritance it bequeaths to his children.

Heredity is an unquestioned fact at this age. We know that qualities of the parents reappear in the child. A child whose father died before it could recognize or remember him will often exhibit the same peculiar gait in walking. If, occasionally, the child will escape such inheritance the grandchild may have it. Some families, from generation to generation, inherit mathematic or artistic capacity. If virtues and great traits are inherited, why should not defects, dispositions to diseases of body or mind, or of both? There is no question that the drunkenness of parents can and does entail the love for drink upon the offspring, or it may at least very decidedly imperil life and health. When we reflect on the fact that inheritance makes the good or bad quality or defect of the parent stronger in the offspring, this matter assumes a far graver aspect.

The craze for drink, the so-called acute alcoholisms, alcoholic mania, dipsomania, delirium tremens, chronic alcoholism, specific alcoholic psychoses—all are classed with mental disorders. As such they can descend to the children. Dipsomania can be transmitted from father to child, or else the effect of such defect in the father may produce an otherwise injured mentality in the offspring. It is astonishing how early this was recognized, for Plutarch uttered this startling sentence: "Ebrii gignunt ebrios"—Drunkards beget drunkards.

Many facts have been collected, all pointing in this same direction.

1. A man became a drunkard after middle life; children born to him before his degradation remained free from the vice of drunkeness, while those born afterward became drunkards.

2. Erasmus Darwin states that diseases inherited from drunkards descend to the third and fourth generations, until, finally, the family dies out.

3. Another observer says that of ninety-seven children of drunkards only fourteen remained free from some defect.

4. Still another maintains that fifty per cent. of

the idiots and imbeciles of great cities are the children of drunkards.

5. The children of drinkers inherit the same or a greater predisposition to nervous disorders than those of nervous or really insane parents. They suffer most frequently in infancy from convulsions and epileptiform diseases.

6. Districts known as "drinkers'-districts" in Europe furnish far fewer good recruits for military service.

7. A law was passed in Sweden against drunkenness, *i. e.*, making it a punishable offence, and since then the number of persons unfit for military service on account of undersize and general weakness has grown much smaller.

8. A distinguished specialist on children's diseases observed ten families of drinkers and ten of temperate parents for a period of twelve years.

The ten drinker-families produced in those twelve years fifty-seven children. Of these, twenty-five died in the first weeks of life, of weakness, of convulsive attacks, or of edema of brain and membranes; six of them were idiots; five were stunted in size, and were of real dwarfish growth; five, when older, became epileptics; one, a boy, had grave chorea, ending in idiocy; five had inherited diseases and deformities, such as chronic hydrocephalus, harelip, and club-foot; two of the epileptics mentioned became, by inheritance, drinkers. Only ten, therefore, of all these fifty-seven, or 17.5 per cent., showed, during youth, normal disposition and development of body and mind.

The ten temperate families produced in the twelve years sixty-one children. Of these, five died in the first weeks, of weakness; four, in later years of childhood, had curable nervous affections; two only showed inherited nervous defects. The remaining fifty, or fully 81.9 per cent., were normal in every way, developing well in body and mind.

My friend, Dr. Vandenburg, has kindly furnished me with a list of forty-four patients treated by him for alcoholism. On examining the notes carefully I find that twenty-five of them had ancestors, or, at any rate, relatives who drank. Of ten of them there was no previous history obtainable. These, very likely, ought to be added to the twenty-five, as it appeared from certain signs that they merely did not wish to expose their family histories.

It is a curious but very general fact, that there exists a sort of instinctive tendency in the members of a family to hide from others as well as from themselves anything that would tell of the defect by a faulty nervous inheritance—I mean an inheritance of defects in the central nervous system. Men do not like to acknowledge the controlling influence of such a fate, and they often instinctively take pains to refer diseases that are unmistakably inherited to very ordinary, accidental, and always different causes. To try to obtain information in such matters from family-members is too frequently a fruitless undertaking. They will often throw impediments in one's way, even leading one into wrong paths; and yet to make a proper diagnosis and prognosis in nervous diseases one must try to learn not only the history of his patient, but also the diseases that are prominent in his family.

But to return to my Vandenburg statistics: four mothers and sisters were tuberculous; one has a father who is very nervous, and smokes incessantly; one has an asthmatic grandfather. Only three have a family record that seems free from all defects. Eleven of them showed tuberculosis or some other lung-difficulty in their families; one had insanity on the mother's side, and of one the father's sister was insane; of one, the uncle and aunt on the father's side were insane; and one had insanity in two aunts on the father's side. There was insanity in the father of one, induced by drink, and in one instance the paternal grandfather drank heavily, the father moderately. In one case the paternal grandfather drank hard and died of apoplexy; the great grandmother was tuberculous and the mother paralytic. In four instances the grandfathers drank heavily, though the fathers were free from the vice.

All of these researches only point the more strongly to the importance of ascertaining the best methods, if there exist any, to check the disease and its ravages.

The establishment of a so-called Keeley Institute in the village in which I reside has brought to my mind with more than common emphasis the subject of treatment of alcoholism, craze for drink, or dipsomania.

It is to be deplored that the State has not created special laws for the legal commitment of drunkards, and erected suitable institutions in which these unfortunates could be confined, treated, and kept not only until well of a debauch, but until their will-power had been reëstablished. The only institution near New York for the treatment of drunkards is not calculated to do all this. There they are simply helped over a spree and set afloat again as soon as sobered and restored to sleep and appetite. Nothing is done to keep them in an appropriate manner for improving or recreating their moral strength, which, after all, is the great point to be worked for. I have sent alcoholic habitués to the insane asylum. This, also, is not a proper place for them, and besides, one has often to strain points to bring such cases before the Commissioners in Lunacy in such a way that they will allow them to be received in an asylum for the insane.

The Keeley system, which I have had much opportunity to observe, has something in it which none of the formerly established systems has ever shown. It tries to reach the mind, and hence to establish on a new basis the dethroned will-power. This is done first of all by an appeal to the patient's honor; and the great success which in the beginning seemed to follow this method of cure was unquestionably due to the fact that the majority of the earliest patients were of the very best class, men willing and anxious to be cured, and whose intelligence was of the better and best type. These patients helped themselves by their desire to be helped. Then there existed a sort of brotherhood among them—a feeling of kindliest interest in each other's improvement. A later arrival, on expressing himself still miserable after a few days' treatment, was strengthened by older patients saying, "It was so with me too, but a few days more will help you." Then, sure enough, in a few days the later arrival would all at once say to himself, "Well, I see these others gave up alcohol; I can do so, too," and he does, and every day carries him farther away from the beverage, and leaves him feeling better and better.

Now, although his mind cured him, he being impressed with the idea that some secret, subtle means has been used to produce this beneficial work, cherishes a growing belief in the marvellous effects of it.

It goes without saying that I by no means advocate the manner of secrecy in which the Keeley system is practised. It is wonderful, nevertheless, to note the many successful cures made by it. What helps to increase in the eyes of the public this success is the ingenious way in which Mr. Keeley himself dismisses his cured patients, or graduates, as he strangely misnames them. Every evening—such is the practice at Dwight—every evening the graduates of that day are requested to step into Mr. Keeley's private office before departing, to receive his final lecture. There he tells them: "Now, gentlemen, remember, I have filled your bodies with a poison inimical to alcohol. If in the next four weeks you return to your old practice of drinking it, this poison which I have introduced into your bodies will kill you by meeting alcohol within you. If you abstain for four weeks, but begin to digress from your present abstemious life, after the fourth week the same poison will make you seriously ill." This is an ingenious plan to make his cases tell on the community, for the patients after their return to their respective homes will be closely watched at first by the people around them; but four weeks escape, and no relapse into dissolute habits takes place. Interest begins to flag, a four-weeks' wonder becomes tiresome, or is no more noticed after another four weeks of continued steadfastness. The best impression is thus left on the minds of the people as regards the Keeley treatment, and Mr. Keeley's clever parting lecture has brought forth the desired fruit.

The great object of my address to you is to rouse this Society into action, to take steps to petition the Legislature to pass the laws I have alluded to, and to vote money for the erection of a building dedicated solely to the restoration of drunkards. How this restoration could be effected, there is no need of bringing plans forward, no matter how long and well matured, until a movement in the direction named has been crowned with success. I feel very strongly on the subject. The compassionate sympathy the condition of drunkards calls forth should impel all of us to forward so good a work as I propose. To institute establishments of this kind will be in the end of immense benefit to the public treasury. Only reflect on the labor power saved by it for the Commonwealth! The skilful mechanic (how often is not the best given over to drink) will be restored to his family, perfectly confident again, and willing to be the breadwinner as of yore.

The unfortunate who, during a crazy spree, has threatened perhaps the lives of people, will no longer go to jail to expiate a sentence in complete idleness, but will speedily be cured of his debauch, and at once resume on remunerative labor in one of these institutions.

It is sad to watch our present system. I will give you just one experience of mine.

A few months ago a prisoner was brought into our jail in a most terrible condition—crazed by drink, with his face beaten into a pulp during self-provoked rows, unwilling to be controlled in any way. The attending physician found him chained close to the floor of the cell, as dangerous and violent as a wild beast. A hypodermatic injection of morphine restored him to his former quiet, and he was soon brought before the court and sentenced to a certain term of imprisonment in the county jail. When the time of his release drew near the judge who had sentenced him requested me to examine him as to his mental condition, for he feared the man was insane, his behavior during his trial having so impressed him. I visited him at once, and found him a most intelligent, wide-awake man, who only a year ago had given himself up to drink, and had ever since lived in constant alcoholic excitement. Deprived of drink, he had perfectly recovered, and felt ashamed of his condition. The jail was not only not the place for him, but it was most detrimental to his moral condition. Thrown into close contact there with criminals of all shades, while his mind was still weakened from the long-continued excessive use of alcohol, the danger

became most imminent that the former drunkard would become a future criminal.

There are people who have no patience with drunkards, just as there are those great masterpieces of virtue who cannot understand how one can ever be led by passion's wild demands from the straight and practical road, whose every step is well calculated beforehand and arranged in an undeviating routine system. But such people are possessed of natures that *cannot* be tempted—cold and self-contained individuals, their virtues are to my mind no virtues at all, for they have never to sustain an onslaught of the evil one. To them I do not turn for coöperative sympathy, but to those scarred in many a battle, won or lost. And it is scarcely necessary that I should portray for such the many ways in which excellent men or women may become almost unconsciously enslaved by alcohol.

Look around you, and see how many homes have been destroyed; how much happiness undermined; how much of grief planted in the hearts of men and women by the unfortunate victims of alcoholic excess, and then you will join in doing this great work in which my whole heart's energies are enlisted.

REPORT OF OPERATIONS UPON HERNIAS.

BY CHARLES S. HAMILTON, A.M., M.D,
OF COLUMBUS, OHIO;
PROFESSOR OF THE PRINCIPLES OF SURGERY, STARLING MEDICAL COLLEGE, AND LECTURER ON CLINICAL SURGERY, MT. CARMEL HOSPITAL.

STRANGULATED HERNIA.

THE operative treatment of strangulated hernia affords one of the best illustrations of the diminished mortality attending surgical procedures since the introduction of antisepsis. If necessary, the sac may be opened with comparatively slight risk of peritoneal infection; and in the majority of instances this step is advantageous, if it is not absolutely necessary. The era of cleanliness in surgery has produced another striking change. The operation is not feared as it was formerly, and on this account is advised at a much earlier period, instead of being regarded as a *dernier ressort*. It is no longer justifiable to resort to prolonged taxis, which may result in additional traumatism to the already inflamed and softened intestine. The unrecorded history of strangulated hernia would doubtless furnish many examples of reduction *en masse*, rupture of gut, and similar catastrophes from long-continued efforts to reduce. The present attitude of the profession might be expressed thus:

So soon as the diagnosis is made, resort to anesthesia with intelligent and gentle taxis for ten minutes, unless it be contra-indicated by stercoraceous vomiting or gangrene. If taxis fail, the anesthetic should be continued and the operation performed at once.

The following group of cases is reported, not with a view to the maintenance of any special method of operating, but in order to record experience in a very interesting and practical branch of surgery:

CASE I.—Mrs. R. J. F., of Columbus, aged seventy-four, had had a small irreducible femoral hernia for five years. On June 23, 1890, while the patient was straining at stool, the protrusion suddenly enlarged. Severe pain was immediately felt in the lower abdomen, and vomiting occurred. During the next few days attempts were made to return the viscus. At midnight on the 25th she was referred to me for operation. At that time she was vomiting occasionally, and there had been no movement of the bowels for three days. Her pulse was 114 and irregular. Her arteries were evidently in a state of calcareous degeneration. Ether was given by Dr. Dennison, and the operation rapidly completed. On opening the sac some blood-stained serum escaped, and a mass of adherent omentum was removed after ligation with strong silk. Partly surrounded by the omentum was a knuckle of small intestine, dark red in color, and with swollen walls; incision of Gimbernat's ligament was necessary in order to return it to the abdominal cavity. The sac was ligated and removed. The patient's convalescence was uneventful in spite of her advanced years and feeble condition. She was discharged from the hospital in four weeks. Hernia eventually returned, but is controlled by a truss, and now causes her no annoyance.

CASE II.—J. McW., of Marion, twenty-three years old, had had an irreducible femoral hernia for two years. On the morning of January 31, 1891, a violent muscular effort was followed by pain at the site of the protrusion and increase in its size. Vomiting commenced at once, and was continued until the evening of February 1st, when I first saw the patient. Dr. L. D. Hamilton, of Marion, had unsuccessfully attempted to reduce under chloroform. The patient's pulse was 115; he was vomiting frequently, and was tympanitic. Under ether, reduction was again attempted, but without success. The usual incision was then made over the length of the tumor, and the sac freely opened. Adherent omentum was ligated and removed, after which a slight incision in Poupart's ligament permitted the return of the discolored small intestine. The peritoneal sac was cut off as near the ring as possible, and the wound closed. The recovery was rapid. The hernia has recurred, but a water-pad truss prevents its descent.

CASE III.—A. D., of Lily Chapel, fifteen years of age, had an undescended testicle in the right inguinal canal. Early in the morning of January 29, 1891, while lifting a heavy basket of corn, he suddenly felt a sharp pain in the groin. During the day he walked five miles. At night the pain became more severe, with vomiting and abdominal distention. Dr. Jewett and Dr. Beach, of West

Jefferson, were summoned, and found an obscurely fluctuating lump in close relation with the retained testicle. Taxis, with the aid of morphine and chloroform, was attempted without success. At daylight on the 31st I found the boy with an irregular pulse of 124, vomiting matter of a slightly fecal odor, tympanitic, and suffering the usual paroxysmal pain between the umbilicus and pubes. There had been no action of the bowels since the 27th. I at once operated. The sac occupied the inguinal canal, and was distended with an ounce and a half of blood-stained serum. In order to expose it, the aponeurosis of the external oblique was freely incised. The testicle was apparently normal. A swollen loop of intestine, nearly five inches in length, and of a red-brown color, was the strangulated viscus, being constricted by the sharp margin of the internal ring. After incision of the ring, and consequent relief to its circulation, the intestine began to recover a more normal appearance, and was returned to the abdominal cavity. At this stage of the operation the patient's circulation became depressed. Free stimulation was resorted to, and the wound was closed after accurate stitching of the divided aponeurosis, no attempt being made to bring the testicle down to its proper location.

After the reduction of the intestine, about six ounces of clear fluid escaped from the abdominal cavity. Notwithstanding the hasty termination of the operation, the patient recovered promptly, passing flatus on the following day, and having a normal evacuation on the second day. At the present time the testicle cannot be felt, having retracted into the abdominal cavity; nor has the hernia at any time returned.

CASE IV.—Mrs. H., of Mt. Gilead, aged sixty-six, had had an irreducible femoral hernia for many years. When I was first called by Dr. Buxton, February 6, 1892, strangulation had existed for twelve hours, taxis having been ineffectual. The protrusion was oval in shape, occupying the right groin; its dimensions, three by six inches. The part was exceedingly tender, and the constant use of morphine had been necessary to control pain. The usual symptoms of strangulated hernia were found, though there had been no stercoraceous vomiting. Ether having been given by Dr. Buxton, operation followed. The sac contained some bloody serum, with a large amount of adherent omentum (the greater part of which was removed), and four inches of the dark-red colored intestine. It was necessary to nick both Gimbernat's and Poupart's ligaments in order to return the gut. After removing a portion of the sac, the remainder was tied close to the ring. Two stitches were then taken to approximate the edge of the enlarged opening, and the wound was closed. The patient recovered with a sinus leading probably to the silk ligature at the neck of the sac. There has been no return of the hernia.

CASE V.—Mrs. C., of Plain City, thirty-six years old, had had a right femoral hernia for a year and a half. It had been strangulated for thirty-eight hours, when Dr. Gardner and Dr. Howland advised operation, after failure to reduce by taxis. She had a high pulse-rate, slight tympanites, umbilical pain, but no vomiting had occurred—possibly it had been prevented by the free use of morphine which her suffering demanded. The sac contained only a knuckle of small intestine of dark-brown color, and much swollen. In this case the constriction was so tight that division without injury of the gut was a matter of some difficulty. The sac was readily excised, and the patient recovered. She is now perfectly well, and wears a truss, although the hernia has not descended since the operation, March, 1892.

CASE VI.—H. M., of Columbus, forty-two years old, had for some years worn a truss because of a right inguinal hernia. On December 17, 1891, while working without his truss, he lifted a heavy weight, and felt something give way in the groin. Intense abdominal pain soon followed, with the symptoms of strangulated hernia. During the day his physician, Dr. Dumm, made efforts at reduction under an anesthetic, but without success. At 10 P.M., the patient was brought to Mt. Carmel Hospital for operation. An incision was made from the region of the internal ring well down to the bottom of the scrotum, as the tumor was very large. A considerable amount of turbid serum escaped from the sac, which contained omentum with fourteen inches of small intestine. The constriction was located at the internal ring. A portion of the omentum was removed, and the intestine carefully examined. Its walls were greatly swollen, and it was almost black in color. The constriction was divided, and the intestine wrapped in warm cloths. Before many minutes there were signs of resumption of circulation, as shown by change of color, and it was then decided to return the gut to the abdomen. It was a question in the mind of the operator at this time whether it would recover its integrity. As usual, the sac was removed and the wound closed.

The following evening the patient's bowels moved freely, and his condition was good until the 23d, when it became necessary to give him morphine occasionally on account of abdominal pain. On the 27th a small fistula formed in the upper part of the incision. From this date until his discharge, on January 15th, he was subject to attacks of pain in the right inguinal region, and after returning to his home he acquired the morphine-habit. Before leaving the hospital, abdominal section, with correction of any faulty condition that might be found, was advised, but his consent could not be obtained.

This man died eight months after operation. The fistula had nearly closed, but the combined effects of fistula and opium, with a constitution impaired by excesses, carried him off.

It is possible that after its return to the abdomen, the strangulated and inflamed intestine became adherent to surrounding structures in such a manner as to narrow its caliber, and that thus it continued to act as a partial obstruction to the passage of intestinal contents. A secondary operation, if permitted at an early date, might have permanently relieved him.

CASE VII.—Mrs. J. D. E., of Columbus, aged

sixty-five, was seized with severe abdominal pain and vomiting on the morning of April 13, 1892, while making some unusual muscular effort. Dr. Coleman saw her on the following day, and found the symptoms of strangulated hernia, with a small, painful tumor in the left groin. The patient had had no rupture until the time of this attack. The taxis having failed, at 6 P. M., on the 15th, operation was performed without difficulty, the hernia being femoral, and containing small intestine with omentum. The recovery of the patient was retarded by intercurrent disease. There has been no return of the protrusion.

RADICAL CURE.

CASE I.—W. E. of Moxahala, twenty-five years of age, had an undescended testicle, with incomplete hernia in the right inguinal canal. The testicle was so sensitive that no truss could be worn; the hernia was growing larger and causing much annoyance. Operation was carried out at Mt. Carmel Hospital, June 15, 1889. The testis was atrophied, and hence removed. The sac was then dissected free from its connections, and McBurney's operation for radical cure completed. The wound healed rapidly, and the patient was discharged a month later. He writes that he has had no recurrence, and does not wear a truss, although he has been advised to do so.

CASE II.—Mrs. K. S , Columbus, aged fifty-two, had had a right inguinal hernia for thirteen years. For a somewhat shorter period irreducible umbilical hernia had also existed. She was a large, fleshy woman, the mother of six children. The protrusion in the groin was fourteen inches in length, and four in diameter, and could not be restrained by a truss. It frequently became incarcerated, and required taxis, with prolonged rest in bed, to effect reduction. McBurney's operation was advised by Dr. Lippit, and performed by the writer in June, 1890, followed for the time being by cure. The patient was advised to wear a truss in order to prevent a relapse, but failed to do so. Within the last two months there has been some sign of recurrence.

It is interesting to note that the umbilical hernia became larger after the operation, and has remained so up to the present time.

CASE III.—Mrs. H. L., of Lancaster, aged fifty-four, underwent operation in February, 1890, for the cure of umbilical hernia of twenty years' standing. The rupture was reducible, the aperture being half an inch in diameter. Operation was advised for relief of distressing gastro-intestinal symptoms incident to the hernia. After removing adherent omentum, and a return of the large intestine to the abdominal cavity, the sac was ligated and cut off short as possible. The edges of the ring were then approximated by a purse-string suture of strong catgut. Additional wire sutures were inserted to relieve tension on the catgut during the healing process. The patient was discharged in five weeks, and the rupture has not returned.

In all of these operations the usual antiseptic precautions were observed. Whenever the condition of the patient permitted, radical cure of the hernia as well as relief of strangulation was sought. The favorable results may be attributed largely to the promptness with which, in the several cases, the general practitioners recognized the condition and urged surgical interference to prevent an otherwise fatal issue.

Operations for the radical cure of hernia are only indicated in special cases, because, as a rule, the cure is not permanent from any of the generally recognized methods.

The following conditions would seem to justify its performance:

1. When the hernia is irreducible and painful.
2. When the hernia is very large, and cannot be controlled by a truss.
3. When the neck is so small that there is constant danger of strangulation.

In all cases a truss should be worn after operation in order to prevent relapse.

THE REASON WHY THE NECK OF THE FEMUR DOES NOT BREAK.

BY BENJAMIN T. SHIMWELL, M.D.,
ADJUNCT PROFESSOR OF OPERATIVE SURGERY, MEDICO-CHIRURGICAL COLLEGE, PHILADELPHIA, PA.

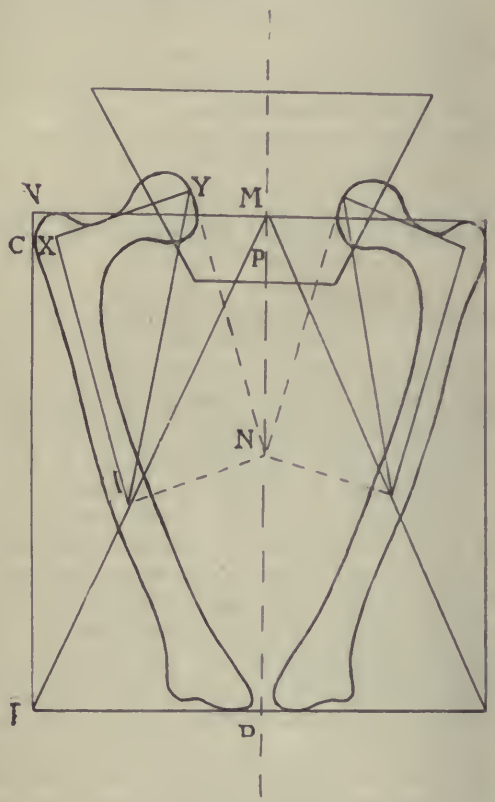
THE clinical study of fractures of the femur due to indirect violence shows a preponderance of breakage within a given area. When we look at the femur as a whole, we are impressed with the idea that the part that would appear most liable to suffer this accident is the neck. The distance of the head from the shaft, by its obtuse angle, would, at the first glance, lead us to suppose this to be the weakest point. But Nature has recognized this, and has made every effort to strengthen it. The arrangement of columns of osseous tissue gives unusual support, and lessens the violence of shock. This arrangement has been accepted as the reason why fractures are not common at the neck. When fractures occur at this point they are confined principally to the declining stage of life, and even then this is, no doubt, due to osseous degeneration and consequent change.

Granting that every provision has been made to strengthen the neck, can we, on careful examination of the femur, say that it is in any other and better manner enabled to hold the trunk? Will not a tubular column stand more direct pressure than any mechanical apparatus constructed on the same principle as the neck of the femur, providing the same comparative size is maintained?

Nature has made no part of the economy by chance. Perfection was reached by means extending over long ages. The very angle which the neck of the femur takes is the keynote in the argument against itself as a factor, as far as strength is

concerned. It is on the ground that all parts of the body are based on definite and distinct laws that I propose to demonstrate by a problem in mathematics that fractures of the femur taking place in the shaft, and not in the neck, are governed by distinctive laws. It is not so much a question of the strength of any part of the bone as it is that of the impact of forces at a given spot.

An examination of the annexed figure shows the presence of two major rectangles and four right-angled triangles, and two minor rectangles and four right-angled triangles. One side of the major rectangles is made by the line of the center of



gravity. The base is formed by a horizontal line extending from great trochanter to great trochanter; then another line is dropped from the outer side of the great trochanters, parallel with the line passing vertically through the center of gravity. These are joined by a horizontal line, parallel with the base, through the knee-joints. This gives the two major rectangles. Then starting at M we carry a line to F, which divides the rectangle into two right-angled triangles. If we now draw a line through the center (Y) of the head of the femur, we find that it strikes the shaft of the femur on a level with the neck at its junction with the shaft (X). This line is carried to the center of the axis of the femur, and then down its length to the point of bisection of the femur, I, made by the hypothenuse of the major right-angled triangle. Then carry a line parallel with the base to N, which strikes the center of gravity, one of the sides of the major rectangles, then up to Y, parallel with X I, and we have a rectangle similar to either of the major rectangles. Then a line drawn from Y to I gives the hypothenuse of two right-angled triangles, both similar to the major right-angled triangles.

The value of the figure lies in the modification of the force of impact by the presence of certain definite laws.

The patient falls either on feet or knees, the force in the illustration being a combination of the weight of the body and the resistance of the object struck. A force travelling to the center of gravity would be the sum of the weight of the body and the resistance of the object, and therefore the impact at the base would be as the sum; consequently the neck of the femur would break, but the presence of the hypothenuse of the major right-angled triangles meeting at the base modifies the impact according to the rule that governs force applied obliquely. In the present case the force is applied in the direction F P, under the angle F P C, against the surface M V. Resolve F P into F C perpendicular to M V, and F D parallel with it, then F C will be the absolute effect of the force, and F P — F C is the loss. To prove the value of this, which applies to the body as a whole, the presence of the same angle in the minor triangle, in which the force is I Y, demonstrates it when applied to the femur proper; consequently, instead of the neck of the femur having to resist the whole force, it is modified, and the explosion or resultant takes place at another point.

The place of explosion is proved by the law: "Two forces not parallel, and applied at different points, may have a resultant, if they lie in the same plane. It is found by extending the lines of direction until they intersect."

The hypothenuse F P of the major right-angled triangle, by the direction of the force, is applied at the center of the base-line M. This is the force applied to the body as a whole. The point of application of the force in the minor angle is at the head of the femur. These forces are not parallel, but on the same plane, the point of application being different. Therefore, the line of the minor triangles, Y I, intersects the line of the major triangles, F P, at the middle of the femur; consequently, the resultant of the force is at this point, and the femur breaks at or about the middle of the shaft.

1253 S. SEVENTEENTH STREET.

OF 1837 cases of cholera among the workmen employed in the breweries of Hamburg, Altona, and Wandsbeck, there were but two deaths—a percentage of 0.12.

A NEW MEASUREMENT IN THE STUDY OF FEVER.

BY LOUIS F. BISHOP, A.M., M.D.,
OF NEW YORK.

IT has occurred to me that in the mensuration of fever we are deficient in terms. Since the beginning of medicine the duration of fever has been observed. More recently we have come to measure its height. It still remains for us to obtain a unit to record duration and height, when considered together.

Not long ago electricians were confronted in a similar way by the need of a unit to express current.

They said empirically that the current produced by one volt against a resistance of one ohm, should be called an "ampère."

In like manner, let us say that the amount of febrile disturbance produced by an elevation of the temperature of the body one degree for one hour, shall be called an "hour-degree."

Thus we have a unit in terms of which we can express the duration and height of any febrile movement.

In the usual graphic method of recording temperature, by means of a curved line upon a chart, if the height of the curve above the normal line represent the elevation of temperature, and the horizontal distance travelled by the curve represent the progress of time, then the area of the chart included between the curved line and the normal line will represent the number of hour-degrees of fever to which the patient has been subjected. Thus an elevation of temperature of one degree for twenty-four hours equals twenty-four hour-degrees. An elevation of two degrees for fourteen hours equals twenty-eight hour-degrees. An average elevation of three degrees for three weeks equals 1512 hour-degrees. If, during twenty-four hours, the temperature fall regularly from an elevation of two degrees to normal, the patient has suffered twenty-four hour-degrees. If the idea be clear, there can be no advantage in multiplying examples.

I am confident that this new quantity, when taken in conjunction with the records already in use, will be of material assistance in the study of cases of fever and of their treatment.

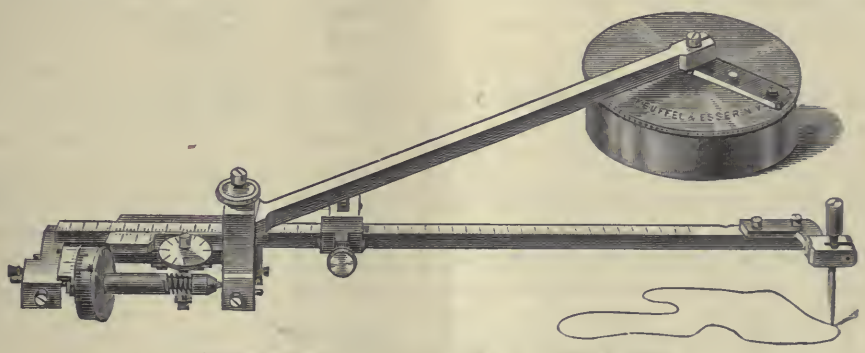
The estimation of the number of hour-degrees represented by a fever-chart offers inherent difficulties. The mensuration of so crooked a figure may well appal the unmathematical physician.

I have devised an approximative method.

In every temperature-chart the printed squares have a definite value in hour-degrees equal to the number of hours apart of the perpendicular lines multiplied by the number (usually a fraction) of degrees apart of the horizontal lines.

Rule: Count the number of whole squares included in the fever-area, and add half the number of squares only partially included. Multiply this number by the value in hour-degrees of one square, and the result will be (approximately) the number of hour-degrees represented by the curve.

A much better method is by the use of an instrument which was brought to my notice by Mr. John A. Roebling, C.E., of New Jersey. The polar planimeter is an instrument used by engineers to measure the area of any figure, no matter how irregular. The instrument is shown in the accompanying illustration.



Polar planimeter. (Copyright, 1887, by Keuffel & Esser.)

The chart being placed upon a flat surface, the needle is passed over the circumference of the figure, and the area is read directly from the instrument in square inches, or for whatever unit the instrument has been set. Having the area of the figure, it is an easy matter to reduce it to hour-degrees. In this way all the charts of a long case can be measured, and the total taken at one reading from the instrument. The value of our results will depend upon the accuracy of our charts. To obtain a curve of much value the temperature should be taken every four hours.

This estimation of the total amount of fever will be of especial value in checking the undue statistical value given to cases with high maximum temperatures which are often due to unimportant causes.

Though the application of this method is chiefly

to the study and comparison of series of cases of which careful charts have been kept, it has an immediate lesson for every-day work.

In any febrile disease the comparison of the number of hour-degrees, from day to day, will convey a much clearer idea of the progress of the case than the mere inspection of a chart, or perhaps of a list of numbers.

After all, the importance of the matter is to bear in mind, from day to day, not only the present condition of our patient, but also what he has already endured.

A procedure which would be proper and useful to a patient in the latter part of an attack of enteric fever, who had endured 1000 hour-degrees, might be fatal to one who had endured twice as many.

Let us, then, consider not only the degrees, but also the hour-degrees; not only the fever-height, but also the fever-area; not only the quality, but also the quantity of the fever.

36 WEST THIRTY-FIFTH STREET.

ANALYTIC NOTES ON LIQUID MALT-EXTRACTS.

BY HENRY LEFFMANN, M.D.,
OF PHILADELPHIA.

FROM brief notices in recently-issued text-books as to the employment of malt-extracts, it appears that the leading therapeutists are not favorably impressed with their usefulness. Nevertheless, if one may judge by the variety of brands now in the market, and by the extensive displays occasionally seen in the show-windows of drug-stores, it must be inferred that either physicians are very liberal in prescribing these preparations or the public has acquired a strong tendency to their use.

It seems advisable, therefore, to make some comparative analytic determinations and some inquiry as to how far any useful physiologic effect may be obtained from them. The primary motive leading to their employment is doubtless to secure the starch-digesting power which is active in malt, due, as is well known, to the enzyme diastase. This body is, however, somewhat sensitive to chemical influences. Its activity is quickly destroyed at certain temperatures, and suspended, if not destroyed, by many substances of the antiseptic class.

It has not been deemed necessary to include in the examination the solid or semi-fluid extracts. These possess diastatic power, are free from objectionable ingredients, such as alcohol or salicylic acid, and by their very nature are not likely to be used except under medical advice. The extracts prepared by the Maltine Co., Parke, Davis & Co., and the Trommer Malt Co. possess decided starch-converting power, and evidently contain notable amounts of diastase. The liquid extracts are mostly alcoholic, so that there is a factor in their use that has sanitary as well as medical importance.

The following samples represent, I believe, the principal brands of liquid malt-extracts sold in Philadelphia. They were obtained for me by a retail drug-house of excellent standing, and were all in unbroken packages, in good condition. I learn that at least one of the larger breweries makes a malt-extract which is furnished to retail druggists in quantity, with a label bearing the druggist's name. I have designated this as "Trade" extract (No. 13). It apparently finds considerable sale.

No.	Brand.	Claims.	Alcohol.	Solid ext grms. to 100 c c.	Salicylic acid.	Diastatic effect.
1	Blair's	No alcohol	None	16.06	None	None.
2	Evans's	Less than 4 per cent. alcohol	3 per ct.	5.35	"	"
3	Dukehart's	No alcohol	Present	25.22	Present	"
4	Genois's	Less than 4 per cent. alcohol	6 per ct.	15.4	None	"
5	Wyeth's	Less than 3 per cent. alcohol	2.98 p. ct.	14 1	"	"
6	Malt-Hopine	.....	Present	8.97	Present	"
7	Hercules	.....	"	10.23	None	"
8	English	Rich in extractive	"	5.24	"	"
9	Wampole's	A trifle over 4 per cent. of alcohol.	7.7 per ct.	12.89	"	"
10	Standard	Absolutely free from alcohol	3 per ct.	9.58	"	"
11	Tarrant's	.....	Present	10.24	Present	"
12	Johann Hoff's	.....	"	8.44	None	"
13	"Trade"	Highest per cent. of extract and lowest of alcohol of any malt extract in use.	3 per ct.	5.1	"	"

The foregoing table does not require much comment. It shows that in three of the brands, Dukehart's, Malt-Hopine, and Tarrant's, a most objectionable ingredient, salicylic acid, is present. This substance, apart from the fact that the commercial article is decidedly poisonous by reason of impurities, is especially objectionable in a malt-extract, for it interferes with several of the digestive ferments. Three of the brands, Blair's, Dukehart's, and Standard, make a special claim for freedom from alcohol, but only the first-named justifies this claim. The claim for richness in extract is seen also to be not substantiated in the two cases, English and "Trade," in which it is made.

As might be expected, no diastatic power was observed in any of the samples. For an exact determination of relative diastatic power it is necessary to make conversions under strictly analogous conditions, in the presence of excess of starch, and measure the sugar formed; but for the determination merely of the presence or absence of active diastase

a qualitative test suffices. It was found that with each of the liquid extracts several hours' action at a moderate temperature was insufficient to convert even very small amounts of starch. In some instances measurements were made of the sugar, and it was found that none was formed by the action on starch, the Fehling figure for the liquid after treatment with starch being the same as that before treatment. As in the case of one of the samples, "Standard," such positive claim is made—the advertisement stating that it is "absolutely free from alcohol"—two samples were tested, and alcohol was found in both.

It is apparent from the foregoing assays that the liquid malt-extracts are mostly beers, that they have but little if any value as either food or digestives, and that several of them are positively injurious. It is a fitting commentary on the situation to note that of two most distinguished American authorities on therapeutics, one recommends that malt-extracts should be given before meals and the other that they should be used after meals. It is worth while noting that as substitutes for beer these extracts are not economical.

Clinical Lessons:
Infirmary for Nervous Diseases of the Orthopædic Hospital.

BY S. WEIR MITCHELL, M.D.,
OF PHILADELPHIA.

[Reported by CHARLES W. BURR, M.D.]

HAVING been struck by the vast mass of interesting and illustrative or strange cases which pass under my eyes at this service and are lost in our gathering note-books, I have made arrangements to utilize a part of them for a larger audience. You are aware that the out-service in this hospital is carried on by the physicians-in-chief, and the care and method of it must, I think, impress one familiar with out-services as somewhat unusual. It has enabled us in the past to produce the many remarkable studies that have become associated with this comparatively small hospital. I need only remind you of the essays of Morris J. Lewis, on Chorea; of Sinkler, on the Palsies of Childhood; of Osler, on the Cerebral Palsies of Children; and of Hinsdale, on Station in Health and Disease.

We have shown, too, that even in hospital-wards the *Rest-treatment* is possible for the poor, and the statistics of such therapeusis, with the singular success that has attended it, would be valuable. I feel glad to say, indeed, that while the papers named, and a host of others, illustrate the careful scientific use made of our wards and laboratory, we never lose sight of the first object of these wards—the cure of disease.

These lessons, therefore, will deal not alone with the many singular cases which are likely to come before us, but also with the therapeutic methods that were (at least some of them) in use here before they were thought possible in hospitals, or that, as I think, are better applied and better known within these walls than outside of them. I have no intention of lecturing at length as to the cases we see, or at least I shall rarely so indulge myself.

The first case I ask you to look at to-day is from Scott ward. Watch her as she enters. Her self-conscious, fixed facies will, or should, strike you. Note her ways. At one moment she seems blind; at the next, she moves with swift ease. Her case is full of these oppositions. I read it, and all of it, now, before her, as she is as to it exceedingly intelligent, and will set us right if we err. Dr. Pershing, of Denver, has greatly helped us as to the early history, and saw with clearness of medical judgment into the true nature of this unusually instructive case, which, owing to its changeful features, has greatly puzzled me. I have now reached conclusions which carry my clear comprehension of the case up to a point beyond which the case itself does not sufficiently yield clinical material for a further advance.

B. L., a woman, forty-two years old, married, applied for treatment October, 1892, complaining of blindness.

Family history. Her mother's father was paralyzed. One of her mother's brothers had hydrocephalus, and was epileptic and blind for a year and a half before his death from typhoid fever when twenty-seven years old. Her father died of pulmonary tuberculosis. One sister died of some spinal disease, said to have been caused by a fall three and a half years previously.

Personal history. The patient has two living healthy children; two others died. She has had five abortions. She does not use alcohol. There is no evidence of syphilis. There never was any serious illness except typhoid fever at the age of fourteen years. For many years the woman has heen greatly troubled by family matters, and especially in consequence of a child's death.

The *present trouble* began in 1887. Soon after a miscarriage she found that it was becoming difficult for her to recognize large objects, while small ones could be seen easily. In reading, she was compelled at last to spell each word, because she could see only one letter at a time. She was fitted with glasses, but no relief followed their use. As time passed, vision grew worse. As the form-fields narrowed she recognized persons, not by their faces, but by their clothing and general bearing. She could see a small piece of silk or a pin upon the floor, but could not recognize large objects.

During the second year she lost, to a great degree, the power of recognizing colors. She could walk perfectly well, and avoided obstacles. During the third year she could still see small objects, but could not tell whether or not a house was completely built, or distinguish a man from a horse. In the fourth year she began to strike against objects in walking, and everything appeared black. She could distinguish between night and day, and even between a bright and a dim light.

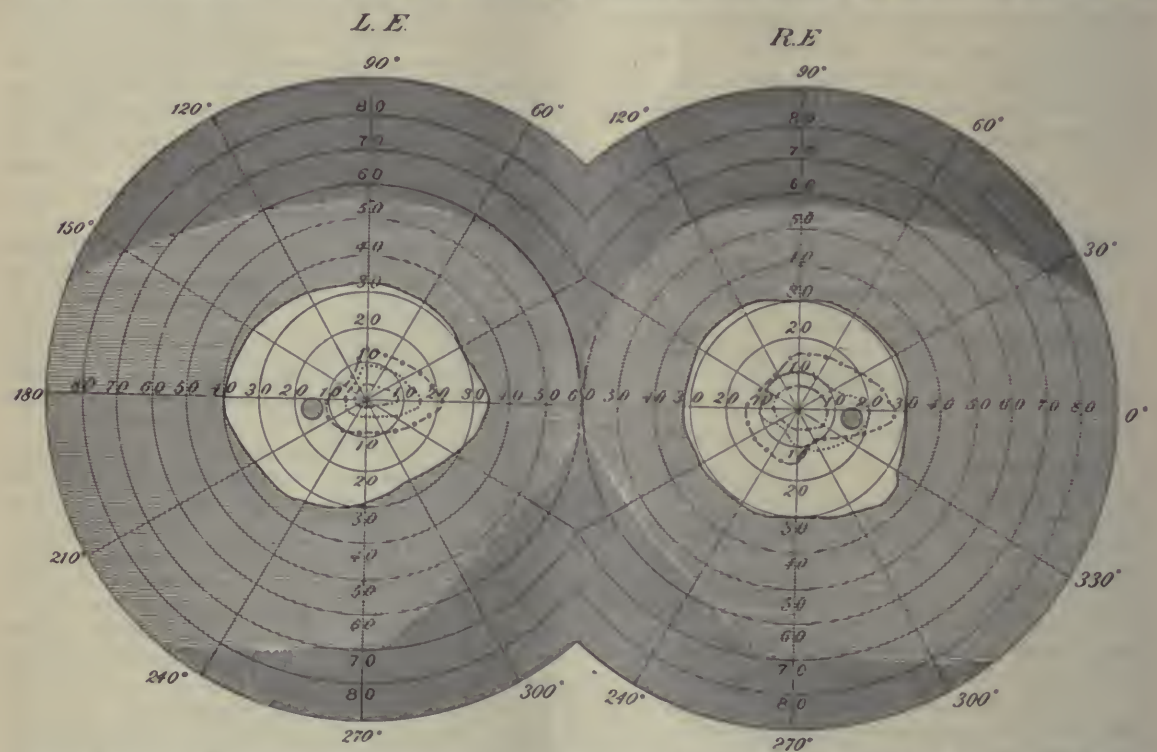
In December, 1891, she was examined and treated by Dr. Howell T. Pershing, of Denver, who has kindly sent us the following additional notes: "She is sent to me as being perfectly blind. Lately she has lost command of words and finds it difficult to carry on a conversation, because words do not come to her mind, and are not understood when heard, though she can readily repeat

them. Recently something was said about a dust-pan and brush. She repeated the words, but had no idea of what they meant until she handled the objects, when the idea came back. She complains of inability to perform the simplest arithmetical operations (but this is inconstant), and also to recognize by touch familiar objects of dress, such as a belt. She consulted Dr. Starr and Dr. Roosa, of New York, in November, 1890. She could not name colors for Dr. Roosa, but a few days later sorted worsteds correctly for Dr. Charles H. Thomas, of Philadelphia,

"*Status præsens.* She recognizes the difference between light and darkness. She cannot count fingers or the windows in the room. The pupils are equal and each reacts to light falling only on the other eye. The ophthalmoscopic appearances are normal. An interrupted galvanic current of one milliampère applied to either side of either eyeball gives a distinct subjective flash. The examination of the other special senses, in all their forms, general sensibility, motion, and the reflexes, shows nothing abnormal. She is not led, and in going out of a room finds the door-knob without feeling for it, though not always. She improved under treatment by massage, electricity, iron, quinine, and strychnine, and moral means. Just before leaving the hospital she told me that she had thought she was totally blind, but she knew now that she could not possibly have been so, because she was in the habit of doing many things for which sight was absolutely necessary. This statement was volunteered as the result of her own reflection. After careful study of the case I was certain it was hysterical." (The accompanying diagrams show the fields of vision taken by Dr. Pershing.)

The improvement in her condition that took place while in Dr. Pershing's care soon disappeared under the stress of family trouble.

Present state (October, 1892). The face, when at rest, is vacant and expressionless. The woman moves about the room with apparent ease, and rarely stumbles against an object. While her gait is not that of a blind person, it also is not that of one with normal vision. When any object is put before her eyes she says she cannot tell what it is. On being told to cross the room and speak to a gentleman standing there, she goes in the proper direction, but is greatly surprised to find, on hearing the supposed man speak, that it is a woman. When a watch is given her and she is asked to tell what it is by touch, she fails. If, however, it is put near enough to her ear for her to hear the ticking, she names it immediately. She fails to recognize a clothes-brush by touch, but when she hears me use it, says: "It is what you brush clothes with—a clothes-brush." The same is true of a finger-brush, except that she calls it a hair-brush. She cannot at first recognize a key by touch, but on being told that it has to do with a door, says, rather doubtingly, "It is a door—door-knob," and then quickly corrects herself, saying, "No, it is a door-key." She fails entirely to recognize a knife by touch. On being given a pencil she calls it a penknife, and adds, "It is what you write with," and does not seem to be aware of her error. At one examination she was entirely unable to tell coins or even to recognize that they were metal, but the next day she recognized a five-cent piece after considerable difficulty, and then quickly told quarters, halves, and dollars. She could not, however, distinguish between a one-cent and a five-cent piece.



Diagrams illustrating the contraction of fields of vision. The continuous line indicates the extent of the form-field in this patient, the broken lines that of the color-fields—blue, red, and green—in the order named. The test-papers were 2 c.m. square.

A pen-holder, with pen attached, she calls a pen. A plate she names properly, but calls a tumbler first a plate, then a bowl, and finally a tumbler. A pin, a needle, a book, a pair of scissors, and a piece of paper she knows instantly by touch, but sometimes not at all. She says that a ball put in her hand is round. when asked its shape, and recognizes a piece of cardboard cut in the form of a circle. She calls a triangular card three-cornered, but all rectangular cards are to her square. An oval she sometimes calls square, sometimes round. After being told several times what an object put in her hands is, she remembers it and answers correctly several days later.

The sense of contact is perfect. There is no anæsthesia. She immediately responds when touched, and can tell the point of a pin from the head, always answering properly "dull" or "sharp." She cannot, however, localize sensation, so as to name the fingers, but can put a finger correctly on the place touched. The pain-sense is normal. The temperature-sense is normal.

If salt or sugar be put upon the tongue, she names the former and says the latter is sweet like candy or sugar, and taste seems to be as to even more delicate flavors normal. Given benzine, cologne, alcohol, and oil of turpentine to smell she claims to recognize them as different, but cannot name them. She says they are unlike. She can write her initials and the first part of her surname fairly well, the latter part being a scrawl. She cannot, however, write any isolated letters except o and c. She describes the latter as o with a piece cut out. If her hand be guided in making letters, she still fails to recognize them. She cannot even write the letters of her name unless she begins at the beginning.

What may be called spontaneous speech—I mean the speech of ordinary conversation—is at the present time normal, though she claims that formerly she misused words. For example, though she may not be able to name an object when given to her, yet if she wants it she will use the proper word in asking for it. Notwithstanding her claim that she has forgotten how to spell, she spells simple words correctly. She also performs simple arithmetical problems correctly. She is nervous, depressed, and at times lachrymose.

Dr. de Schweinitz has examined her eyes and reports as follows: "There is divergent squint in the right eye. The pupils are large, reacting slowly to light; the right very sluggishly. The discs are grayish-red. The veins are full; the arteries are small—the smaller in the right eye. There is lack of fixation, but the patient sees light in all directions. The right eye open (the left closed) perceives objects to the left of the median line and sometimes in the middle, but not to the right. The left eye open (the right closed), perceives objects to the left and in the median line, but not to the right. There is partial right lateral hemianopsia. Given cards to sort, she matches blue ones correctly, but confuses red and green and all others. It was impossible to take the color-fields." All symptoms are worse during menstruation.

REMARKS.—A few preparatory words may make easier for you my after-explanations. We associate with known objects their possession of certain qualities of dimension, form, texture, color, etc. These objects are mentally classified and labelled—a pencil, a box, a hat, and so on. When, again, we see or handle one of these objects, and find by sight or touch that it possesses a group of qualities, we must determine on the label, after swift comparison with our museum of already collected complex memories of things already seen, or handled, or both.

It will help us to look at this problem in the most simple form. When we examine by sight or touch a familiar object, a single hint, as it were, may suffice, as the tick, which suggests a watch. If the object be very novel, or we puzzled, the examination as to the determinative properties and their associations and degrees may be long and difficult. We store away these acquisitions for comparison in certain cerebral centers, visual or tactile, or both.

As regards olfaction, the questions the examinative sense can ask and answer are limited. Usually, in most of the non-pungent odors, one single quality is perceived, and from it the individual reasons by comparison with past memories of scents, and declares the label he is accustomed to assign to the odor in question. This is very simple, compared to the complexity of the properties, and their variation in degree and amount, by which visual and tactile recognitions are made.

In persons who are "*mind-blind*," as Munk called it, "the thing put before them is seen, but suggests no corresponding psychical idea." Now what is here meant by being seen is one of two things, or both together. The thing seen may be present to the man as an image is to a mirror, for the mirror has no memory, and cannot compare the present with the past; or else it is meant that besides this the object so seen may present recognized qualities, but that the patient has no power to place these for comparison with those of other periods. In the one case he merely sees the object; in the other he defines its qualities. In neither case can he label the object or say what use it has, although he may occasionally do this latter, even when he cannot name it. The object may be seen, its qualities compared with older memories, its nature or use be thus known, and yet the power to label it with the vocal sign we call a word be lost.

These sets of conditions are all seen in this case at times. Thus, I blindfold the woman, and offer to her nose vinegar, cologne, asafœtida, valerian. She says they are different; does not take one for another. In other words, she does not say all alike are odors without difference. But a clear perception of the single quality so felt as different in each cannot be lodged in relation to former knowledge for comparison. Hence it has no distinctiveness and cannot be labelled.

It is interesting to study this simple case, and then that of sight. Here the partial general blindness and the added hemianoptic imperfection complicate matters, and these conditions vary from day to day. You will remember, also, that all color-sense is dead, except as to blue, and that the form-field is much contracted. Still, at times she can see the hands of a watch—not, however, so as to tell the hour. At her best moments, she may appreciate qualities sufficiently to say that one thing is larger than another, but not so as to say that this is round or square. At these times she is able to distinguish one person from another, but never to label them until they speak. In her worse ocular states, she cannot distinguish any form of qualitative difference. You will remember that

Dr. Pershing describes her as having been at one time word-deaf, as now she is word-blind.

This trouble is better known and more often seen than the yet more curious form of defect as regards touch. Remember that she can tell heat, cold, touch, pain in all degrees. Occasionally she spontaneously describes a test-object; more often she does not, and yet is able, as the stated inquiries show, to answer correctly all the queries competent to describe an object. Very often the final question, What is it? she cannot answer; or else, and rarely, says what it is for, but not its name. At other times she cannot reply as to the qualities as told by touch alone, or tell scissors from a corkscrew, a book from a watch; and yet tact is perfect. This corresponds to mind-blindness. She is mind-touchless. There is psychic anæsthesia as to touch; or, to be more accurate, either this is true or else she has lost the power of mentally comparing new sensations with the stored memories of those long acquired.

I have not spoken of the localities involved in this triple loss. As to this, our knowledge is still incomplete, and cases of hysterical representation of these singular symptoms are least of all suitable to help us. And certainly this patient is an hysterical illustration of mental incapacities to use the information won through smell, sight, and touch; and, as I am sure such cases are very rare, I have thought it worth while to state for you the reflections which it has brought to my mind. Dr. Pershing had reached a like conclusion early in the case. Of course, these cases all have alexia and agraphia. It has been suggested that the various memorial incapacities, such as the total loss of knowledge of localities or of individuals, may be limited forms of mind blindness, as if one room in the many mansions of memory were suddenly walled up and blocked; but these are, I think, yet more complex conditions of psychic disorder, and only a part of them may fairly be referred to the fount of mental trouble which this case exhibits in so many varieties. Finally we need a better term than *mind-blind*, and a good word for the corresponding condition in which touch and smell are involved.

It has seemed to me that all of these curious states of consciousness as to objects seen or felt, may be represented in the changing psychic development of a child—objects seen in early life are first represented as on a mirror; later, the qualities are defined; and lastly, these are labelled.

MEDICAL PROGRESS.

A New Operation for the Radical Cure of Hernia.—O'HARA (*British Medical Journal*, No. 1667, p. 1279) reports the employment of a new procedure in the operative treatment of hernia. After the preliminary incisions are made, and the vas deferens is freed, a long, strong carbolized gut or sterilized silk ligature is tied around the neck of the sac; a second ligature of finer material is placed about a quarter of an inch lower down, and the neck of the sac is divided between the two ligatures. The index finger of the left hand is then introduced as far as possible into the inguinal canal, in front of the peritoneum, and, there being no important structures between the tip of the finger and the abdominal parietes, an incision is made through the skin only, from without, at a point corresponding with the tip of the finger within. This point is selected for fixing the stump, and is in most cases from two to two and a half inches above the internal abdominal ring. A guarded needle, threaded with one of the long ligatures attached to the neck of the sac, is now passed up the canal on the finger to the point selected for fixing the stump, and driven through the parietes. The needle, having been unthreaded, is withdrawn, to be threaded again with the other end of the ligature, and is reintroduced into the canal, and brought out at a point a little above that at which the first was brought out. The two ligatutes are then firmly tied, the ends cut off, and the sac is thus secured. A decalcified bone drainage-tube is now introduced into the canal, and the margins are laced together over it with silkworm-gut ligatures. The superficial wound is brought together with horsehair, and an antiseptic pad is applied, and kept in place by means of a spica bandage. The plastic inflammation resulting from this procedure causes a sufficient narrowing of the canal to prevent a recurrence of the hernia. The neck of the sac, which had moulded itself to the canal, is removed to a safe distance, and cannot encroach upon the orifice during the process of narrowing, and new structures overlie the internal opening. The bone drainage-tube, lying as it does alongside of the vas deferens, prevents any undue pressure being made upon this when the margins of the canal are laced together, and its presence causes an aseptic irritation, favoring a mild inflammatory process, and at the same time acting as a drain, should drainage be necessary. The opinion is expressed that the operation may be safely undertaken as early as the twelfth month of life, if the hernia is so large as to affect the child's health, or that a truss cannot be borne. The operation has been performed sixty times in males ranging from fourteen months to seventy-five years of age, and was in all cases followed by recovery, and none required the reëmployment of a truss or other abdominal support.

The Etiology of Whooping-cough.—At a recent meeting of the Berlin Medical Society, RITTER (*Deutsche med. Wochenschrift*, No. 45, 1892, p. 1020) reported that he had succeeded in isolating from the bronchial secretion of a number of cases of whooping-cough a diplococcus which he believes to be etiologically specific. The matters expectorated after a typical paroxysm of coughing were received into a sterile vessel and examined at once. The sputum was washed with distilled water, and the milky-white lenticular masses that were present were picked out and teased. Cultivation on agar developed diplococci, which, introduced into the air-passages of a tracheotomized dog, gave rise to cough and a fatal broncho-pneumonia. The bronchial secretion of this animal inoculated upon another gave rise to transitory illness. The organism is aërobic. It does not develop below a temperature of 86°, or above one of 107.6°, and stains well with the basic anilin colors. It is small, and can, with certainty, be distinguished from the pneumonia-cocci of Fraenkel. The number of organisms seems to correspond with the stage of the disease. In cats and young dogs inhalation of pure cultures of the organism was followed by a cough closely resembling that of pertussis.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 28, 1893.

REVISION OF THE CODE OF ETHICS.

A CORRESPONDENT writing to the *Journal of the American Medical Association* (January 14, 1893), deprecates any revision or modification of the Code of Ethics, and objects to the suggestions embodied in an editorial in THE MEDICAL NEWS of September 17, 1892, on various grounds.

We have no word to say against the Code as it stands, except that it contains unnecessary matter that obscures its meaning, and that its provisions fail, in certain respects, to meet the present requirements of the profession. However, we should approve of the Code as it is were it not that there exists a very vigorously expressed dissatisfaction with it on the part of a formidable minority of the profession. Of course, as a "Conservative Member" says, it would "be gracious for the minority to abide by the general sense of the profession and allow the Code to stand as it is, for it wrongs no man"; but the minority emphatically refuses to act in this gracious manner. In the State of New York, ten years ago, the minority repudiated one of the essential provisions of the Code, and secured the adoption by the State Society and most of the affiliated County societies, of what is known as the "New Code," which provides that "members of the Medical Society of the State of New York and of the medical societies in affiliation therewith, may meet in consultation legally qualified practitioners of medicine." In the State of New York, legally qualified practitioners of medicine include homeopaths, eclectics, botanics, and others who are considered irregular. This action led to the most bitter contest or division in the ranks of the profession that has occurred since our recollection.

It is not logical to assume that the sentiment which so divided the profession is confined to the State of New York. While time has practically healed the schism as far as personal relations of members of the profession to one another are concerned, the old societies in the State of New York are without representation in the American Medical Association, and they include many eminent and valuable members. A blind adhesion to the Code exactly as it stands, in view of the attitude of the minority, is little short of fanaticism, and is hardly less reprehensible than the extreme action of the advocates of the "New Code." It seems to us to be the plain duty of the Committee of Revision to endeavor to frame a Code which will unite the profession and be universally adopted by State organizations. To assume that an overwhelming majority of the profession is opposed to any change in the Code is illogical and not in accordance with the facts. In the State of New York only has there been an expression of opinion on the Code. We have before us a "catalogue of the members of the medical profession in the State of New York, showing their vote on the Code of Ethics," published by the "Central Organization of the New York State Medical Association to uphold the National Code of Ethics," in 1884. The Association seems to have made a careful canvass of the profession in New York, having reached by correspondence 5002 regular practitioners of medicine. The corrected results are the following:

For the National Code	2547
For the New Code	1040
For No Code	239
Unclassified	34
Uncommitted	1142
Total	5002

The "unclassified" include those whose replies were indefinite; and the "uncommitted" those who did not respond to repeated letters of inquiry. As the general result of this investigation, it appears that, out of 5000 regular physicians in the State of New York, one-half gave in their adhesion to the

Code as it now stands; more than one-quarter repudiated the Code; about one-quarter were unwilling to take one side or the other, or were indifferent. Does not this showing indicate so considerable a dissatisfaction with the present Code as to call for serious consideration on the part of the central medical organization of the United States? The appointment of a Committee for Revision of the Code is conclusive evidence that such is the opinion of the American Medical Association.

In the editorial of September 17, 1892, THE MEDICAL NEWS advocated a short Code embodying "rules of conduct that are simple, distinct, and easily understood"; a clear definition of the terms regular and irregular practitioners; and a clause especially which will indicate what is meant by a consultation, and lay down the conditions under which a regular physician may give advice to a patient under the care of an irregular practitioner. The last is the one question upon which the opinions of the profession are divided; and it is the provision in the Code relating to this question which has subjected the profession to criticism by the public on the grounds of intolerance and inhumanity. On this point we suggested the following:

"2. A physician should not meet in consultation with an irregular practitioner, or be associated with such an one in the treatment of a patient; but he may properly examine a patient and give an opinion or advice to the patient or friends, or perform a surgical operation, in the case of a patient under the care of an irregular practitioner, without consultation or professional association with such practitioner."

We still believe that, if some such provision were adopted by the American Medical Association, it would completely heal past dissensions, and do much to prevent differences in the future. At all events, the question involved is one that must be met and fully discussed.

It must be recognized that, practically, the Code is for the profession and not for the public. The public does not care for or read the Code; and, as a rule, the few who have any knowledge of its provisions ignorantly regard it as intolerant, and in a certain sense inhuman. It is not essential that a perusal of the Code should give "pleasure as well as instruction"; but it is essential that a Code should be perfectly distinct and unmistakable in its provisions, like any other code of laws. "A Conservative Member" misquotes us in one regard. We take the ground that: "It (the Code and not the public) has nothing to do with acts on the part of physicians that render them amenable to penal law." The Code is for the regulation of professional conduct; and any professional conduct that would render a physician amenable to penal law, would necessarily be in violation of the Code of Ethics.

We do not discuss the question of revision of the Code in anything approaching a controversial spirit. We have cited the contest in the State of New York as affording the only example in which there has been a decided expression of opinion on the "Code question"; and we hope that the deliberations of the Committee on Revision and the action of the American Medical Association will be so dispassionate and wise that the unfortunate experience of the profession in New York may not be repeated in our own or in other States, or similar dissensions find a place in the proceedings of the Association. We wish it to be distinctly understood, also, that, as between the Old Code, New Code, and No Code, as these terms are understood in the State of New York, we should be in favor of the "Old Code."

THE VIRULENCE OF GONORRHEA.

IT has long been well known that gonorrhea may be attended with various disastrous complications in consequence of the extension of the morbid process by continuity of structure. Thus, in the male there may be epididymitis, orchitis, prostatitis, cystitis, ureteritis, pyelitis, pyelo-nephritis, and, as ROBINSON (THE MEDICAL NEWS, August 7, 1892, p. 149) has shown, involvement of the seminal vesicles; and in the female, besides vaginitis, urethritis, cystitis, ureteritis, pyelitis, and nephritis, there may be metritis, salpingitis, and peritonitis. Not at all rarely, too, the inguinal glands are found to become enlarged and sometimes to undergo suppuration.

The affection inappropriately and ambiguously designated gonorrheal rheumatism has been ascribed to "metastasis," a term that was of the most vague significance until the bacterial origin of the infectious diseases received recognition. In the past it was generally accepted that gonorrhea was unattended with endocardial complications, but there is growing evidence to the contrary. This fact has been insisted on by the late DR. MACDONNELL, of Montreal (*American Journal of the Medical Sciences*, January, 1891, p. 1), and the cases recently reported by RUGG (*Lancet*, No. 3605, p. 772) and

HIS (*Berliner klin. Wochenschr.*, No. 40, 1892, p. 994) support his contention.

Various manifestations referable to the nervous system have also, from time to time, been reported in association with gonorrhea. These have been variously attributed to reflex influences, to peripheral neuritis, and to meningitis and myelitis, but there are few records of post-mortem findings. In this connection LEYDEN (*Zeitschrift f. klinische Medicin*, B. xxi., H. 5, 6, p. 607) has reported an interesting case and refers to others. A man, twenty-seven years old, was suddenly seized with symptoms of myelitis, which, in the course of little more than a week, proceeded to a fatal termination. During life a urethral discharge was observed, and in the secretion gonococci were detected. After death a meningo-myelitis in the dorsal region was found, while the mucous membrane of the bladder and the adjacent peritoneum, as well as the kidneys, presented the evidences of an extension of the inflammatory process. Gonococci could not be demonstrated in the lesion of the cord. In the cases of joint-complication and cardiac involvement, also, it has not been possible to demonstrate unequivocally the presence of gonococci at the seat of the secondary lesions; so that the presumption seems reasonable that these are but manifestations of an intoxication resulting from the absorption of the products of the biologic activity of the gonococci.

The observations here referred to will, in part, explain why in so many cases of chronic valvular lesions of the heart it is not possible to elicit a history of antecedent acute articular rheumatism. Without in the least attempting to belittle the rôle played by rheumatism in the etiology of endocarditis and valvular disease, we venture to express the opinion that the articular disease has been held responsible for many lesions that could readily have been ascribed to other influences. With a growing familiarity with and a more extended knowledge of the nature of the infectious diseases, we are learning to place the etiologic burden of an accumulating number of cases of inflammations of serous structures, together with their sequelæ, upon such diseases and conditions as enteric fever, pneumonia, diphtheria, erysipelas, influenza, and puerperal infection; scarlatina and chorea, by reason of their occult relationship with rheumatism, already belong in this category, and in this connection it is interesting to note that there is a growing tendency to look upon chorea as an infectious disease and naturally dependent upon a specific microbe.

In all infectious diseases, therefore, the possibility of secondary involvement of the serous membranes should be constantly borne in mind, in order that the complication may, as far as possible, be guarded against, and that it receive appropriate treatment should it arise.

A HOSPITAL IN PHILADELPHIA FOR INFECTIOUS DISEASES.

IF personal and political intrigue shall be rigorously excluded from its organization and management, a city hospital for infectious diseases, such as has been proposed by the *Public Ledger*, will be a public benefit.

The removal of the Almshouse from Blockley, leaving the entire plot of ground and such of the buildings now on it as may be properly available to be utilized for hospital purposes only, and the construction of isolating pavilions in sufficient number on the vacant lots still owned by the city in the vicinity of the Philadelphia Hospital, would be the best solution of the question.

The pavilions should be so constructed that they may be destroyed and replaced at appropriate intervals. A special operating-room and a special ward fully equipped with appliances for supply of steam and other necessary adjuncts, such as has been in use until recently at the Children's Hospital, should be set apart for cases of diphtheria and croup.

In considering what is the best means to stamp out diphtheria in the city, and in endeavoring to improve sanitary administration in general, however, it is important that the profession should be united and deliberate; that personal interests, ambitions, or resentments should not be allowed to dictate action or to prevent the best means and methods from being chosen; that all questions of "practical partisan politics" be kept resolutely out of the circle of influence. Only thus can permanently useful results be accomplished. "Dickering" with politicians, medical or non-medical, even for a good end, is like making palliative topical applications in a case of luetic ulceration—it leaves the cause of the lesion to continue its destructive activity faster than the local manifestations can be relieved. Whether the proposed hospitals would fall under the administration of the present efficient Board of Charities, or that of the Board of Health,

is a minor matter. Physicians should insist upon the entire separation of the Health Board from politics, and the appointment to all offices connected with the sanitary administration of the State and city of thoroughly qualified experts, and of such only. Unless we are wise enough and bold enough to do this, neither a hospital for infectious diseases nor anything else we can propose will be of much service.

SELECTIONS.

TOO MANY MEDICAL JOURNALS, COLLEGES, ETC.

WE quite agree with THE NEWS as to its statement of facts. There are too many medical journals; too many journals run solely for the benefit of advertisers, for the advancement of some one or more doctors irrespective of the good of medical art and science. There is a vast amount of material published that would never see print if but one-fourth as many journals were published. Doctors who can write good papers do not receive such compensation as they would if the number of journals were less and their quality better.

However, as we see it, this is the way in all similar matters. Of medical colleges there is a vast surplus over the requirements of the medical profession. The damaging effects on the profession are quite as far-reaching and disastrous as in the case of the superabundance of medical journals.

Of medical men there is a great surplus of the lower varieties. These interfere with the work and destroy much of the success of the better sort.

Of medical books what shall we say farther than that the multiplication of the lower grades is disastrous to all concerned?

So we might continue the list. There is too much poor truck of all sorts in the world. But what shall we do about it? This is the question that has puzzled us for many years. In general, where the carcass is, there the vultures will congregate and satisfy their hunger. To be rid of vultures, it is necessary to have no carcasses. So to get rid of these low-bred and ill-conducted journals, colleges, etc., it will be necessary to prevent the accumulation of material whence they derive their sustenance. This is a task that well may discourage the most enthusiastic reformer. However, much has been done, more is now doing, and the line of march is onward and upward. *Amer. Lancet.*

A CODE OF ETHICS.

THE code of ethics adopted by the American Medical Association has not given satisfaction to a certain section of the consultants and specialists of the State of New York, the reason being that they wanted a free hand, so as to be able to meet any practitioners, and not to be bound by any code of honor. We have some of the same class in this country to whom ethics are distasteful, all being fish that come to their net. It may be that the American code of ethics is not quite in harmony with the temper of modern times, and that it might be revised so as to bring it more in accordance with the spirit of the age, but there cannot be a doubt that when it was originally framed it was an admirable code, just to the patient in whose interests it was promulgated, and just to the medical attendant. It is very true that gentlemen require no codes, but, unfortunately, the medical profession is not all composed of gentlemen. Pains and penalties are required to keep a certain class in the right way, and the fear of professional ostracism acts as a healthy stimulus to right action. Society is controlled by its police; a recognized code, with attendant and prospective punishment for ill-doing, is absolutely required in a profession which provides such open portals, and we trust that the executive of the American Medical Association, even though they revise, may not weaken the honorable code handed down by their forefathers.—*Provincial Medical Journal*, xii, 133, p. 44.

REVIEWS.

ANATOMY. A Manual for Students and Practitioners. By FRED. J. BROCKWAY, M.D., and A. O'MALLEY, M.D. (The Students' Quiz Series.) Philadelphia: Lea Brothers & Co., 1892.

To compress within the limits of some three hundred and fifty pages of a Quiz book the essential facts of human anatomy is a task attended with no ordinary difficulties. In the effort to furnish a series of answers to such questions as "Where is such and such a structure?" or "How is a given organ described?" there is an ever-present danger of condensing too much, or of abbreviating to such an extent that the amount of information actually given may be very superficial. Anatomy is a branch of study of such prime importance that the student cannot afford to form other than an intimate acquaintance with it. In order to succeed in this he must be faithful in his attendance in the lecture-room, patient in the perusal of a standard text-book, and diligent in his work with scalpel and forceps at the dissecting-table. Now, although there is no substitute for these, the Quiz manual has its place as a most useful accessory.

This fact has evidently been appreciated by Dr. Brockway and Dr. O'Malley while compiling the book which they have just written. They claim, however, to present, not a duplicate of already existing anatomic compends, but a modern anatomy. In carrying out this purpose, the descriptions are given in a style which, although terse, is more explicit than could justly be expected of a book that merely essayed to be a compend. Throughout the sections on osteology and arthrology the excellent plan has been adopted of interspersing, in type smaller than that of the main text, the descriptions and classifications of Henle where they differ from those of English authorities, important points in comparative anatomy, and useful information as to function. A summary of the osseous homologies of the upper and lower extremities is a feature which will doubtless prove an advantage. In the section on myology, in addition to the older names for the muscles, those which have been agreed upon by the German Anatomical Society will also be found; and anomalous conditions are given in smaller text. This section, too, is concluded with a summary of the homologies between the two extremities.

The sections on the vascular, nervous, and digestive systems are all that could be desired.

At the end of the book is a glossary giving the pronunciation, derivation, and definition of anatomic terms which will prove of great value. It is to be hoped that it will often be consulted, and that it will be the means of correcting some, at least, of the frequent mispronunciations that one hears.

Altogether, the writers of this manual are to be congratulated upon the excellence of their work, and we predict for it a wide and favorable reception.

A PRACTICAL TREATISE ON DISEASES OF THE SKIN. By JOHN V. SHOEMAKER, M.D. Second edition, revised and enlarged, with chromogravure plates and other illustrations. Pp. 859. New York: D. Appleton & Co., 1892.

THIS second edition of the Treatise is a decided improvement upon the first edition. A general revision is noticeable, together with the addition of much new matter, most of which is in the line of therapeutics. Of the more recent remedies that have been brought forward in the treatment of cutaneous diseases, the medicated soaps, manufactured on such an extensive scale in Germany, are specially referred to. The author is firmly impressed with the value of the oleates, and gives a long list of these preparations, from which it would seem that they are applicable in many diseases.

Sodium sulfoleate is also mentioned as being useful as a solvent for many drugs, especially sulfur and chrysarobin; and, if its water is driven off, it may be employed as an ointment-base. Lanolin is also esteemed. Hydrastine hydrochlorate, erythroxylon coca, naphthol, thiol, tumenol, and jequirity are all specially mentioned as being useful. The last-named is regarded as a powerful remedy of the utmost value in specific ulcerations, indolent, scrofulous, and epithelial ulcers, and in ulcerating lupus. It is an irritant, and soon sets up severe local inflammation. The pastes are referred to, but the author does not give them the high rank they deserve. Syphilis is taken away from the neoplasmata and classified with the inflammations, between erysipelas and the acute simple erythemata.

In the treatment of that common and often rebellious disease, eczema, a great variety of drugs and formulæ are prominently brought forward—too many, we think. The practitioner will find it difficult to make a selection from the list, so highly praised are most of the remedies. The details as to the mode of application, and the varieties of the disease for which certain formulæ are suitable, might advantageously have been pointed out more definitely. The mass of material, in the way of drugs and formulæ, introduced into this chapter is not sufficiently digested. Something more than a mere enumeration of the drugs is demanded; we should be told as well how to use them to the best advantage. Indeed, this criticism applies to the therapeutics throughout the volume. Too many diverse remedies are cited without the indications for their employment being made sufficiently clear. The practitioner is consequently bewildered, and runs the risk of selecting the wrong remedy for his case. Quotations and references, especially foreign, are abundantly interspersed throughout the pages. The precise sources of the information, however, are not always given —omissions that impair the value of the book as a work of reference. American dermatology does not receive the cordial mention it deserves.

Some woodcuts and several admirable photographs enhance the value of the work. A copious formulary, occupying many pages, constitutes the last chapter. The general appearance of the volume is, in all ways, creditable to the publishers.

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN ANATOMISTS.

Fifth Annual Session, held at Princeton, N. J., December 27, 1892.

DR. HARRISON ALLEN, of Philadelphia, President; DR. D. S. LAMB, U. S. A., Secretary.

The following were elected to membership: Herbert S. Birkett, M.D., Montreal, Canada; Tracy Earl Clark, B.S., Ft. Plains, N. Y.; J. Milton Greenman, Philadelphia, Pa.; C. A. Hamann, M.D., Philadelphia, Pa.; James W. Hartigan, M.D., Morgantown, W. Va.; George S. Huntington, M.D., New York City; Peter J. McCourt, M.D., New York City; Wm. B. Scott, Princeton, N. J.; Wm. Anderson, F.R C.S., etc., London, England, and C. S. Minot, S.D.

The Executive Committee, through the Secretary, reported that the circular in regard to information concerning the negro race was nearly ready.

The following papers were then read:

1. "Crania of the Cetacea."

2. "The Human Lower Jaw," by Dr. Harrison Allen, University of Pennsylvania.

These two papers were illustrated by specimens, and discussed by Prof. Herrick, and also by Prof. George Macloskie, of Princeton University.

3. "History of the Development of Bone Tissue;" illustrated by microscopic slides, by Dr. Carl Heitzmann, New York City. Discussed by Professors Macloskie and William Libbey, Jr., of Princeton University.

The President, DR. ALLEN, then read his Annual Address, from which the following quotation is made:

"It is now four years since the Association of American Anatomists was founded with a list of fifteen members. Many were the objections raised when it was proposed to organize a new society. Eminent professors declared that it was not needed; others, while sympathizing with its objects, were convinced that the list of members would be so small that it would be a difficult matter to fill the necessary offices. The fact that an active membership exists of ninety-four persons, representing twenty-two States, the District of Columbia, and the United States Army, sufficiently meets both the above-mentioned objections. It tells us unmistakably that the society is needed, and that not only are the offices filled, but that the Association is recognized as a devoted band of students, whose activity compares favorably with that of other scientific organizations.

"But the work thus far accomplished is but the harbinger of what it is hoped may be undertaken. An attempt at coöperation between the American Anatomists is to be brought before you at this meeting. The Executive Committee will present a plan by which observations on the anatomy of the negro shall be entered upon. It

is earnestly hoped that every teacher and demonstrator of anatomy in the country, whether a member of this society or not, will assist its committee in accumulating observations on this class of subjects."

4. "An Anomalous Development of the Human Sternum," specimen and remarks, by Dr. D. S. Lamb, Army Medical Museum, Washington, D. C. Discussed by Dr. Dwight. 5. "Discovery of an Ossified Thyroid Cartilage and a Supposed Rudimentary Clavicle in an Artiodactyl," by Prof. Wm. B. Scott, Princeton University; specimen exhibited. Discussed by Prof. Cope and Dr. Allen. 6. "Observations on the Psoas Parvus and Pyramidalis," a study of variation, by Dr. Thomas Dwight, Harvard Medical School. 7. "Significance of Percentages in Reversions in Human Anatomy," by Prof. H. F. Osborn, Columbia College, New York City. Discussed by Prof. Cope and Drs. Dwight and Lamb.

3.00 P.M. Session resumed. The following papers were read: 8. "Histogenesis in the Brain, and its Bearings on Development and Decline," by Prof. C. L. Herrick, Dennison College, Granville, Ohio. Discussed by Drs. Heitzmann and Piersol. 9. "The Metapore or Foramen of Magendie," with photographs, by Prof. B. G. Wilder, Cornell University. In the absence of Prof. Wilder, the paper was read by Mr. Clark. Discussed by Prof. Herrick. 10. "Neuromerism and the Cranial Nerves of Ophidia," by Prof. Herrick. 11. "The Insula of the Pig," with specimens. Discussed by Drs. Allen, Dwight, and Spitzka. 12. "Note on Diagrams of the Spinal Cord," by Dr. J. T. Duncan, Toronto, Canada. Read by the Secretary and referred to the Committee on Nomenclature. 13. "Duration of Motion of Human Spermatozoa," by Dr. George Piersol, University of Pennsylvania. Discussed by Drs. Spitzka and Heitzmann.

THURSDAY, DECEMBER 29, 1892.

The report of the Committee on Nomenclature, Dr. Wilder, secretary, was presented. The reading of the report was dispensed with, copies having been placed in the hands of the members present.

The following papers were read: 14. "The Innervation of the Organ of Corti," by Howard Ayers, Ph.D., Curator of the Lake Laboratory, Milwaukee, Wis. Microscopical slides, with remarks. 15. "The Posterior Surface of the Liver; described by Vesalius," by Dr. F. H. Gerrish, Bowdoin College, Maine. Discussed by Drs. Dwight, Allen, and Heitzmann. 16. "Embryos of Bats," with specimen and plates, by Dr. Allen. Discussed by Profs. Cope and C. S. Minot. 17. "Meckel's Diverticulum," by Dr. D. S. Lamb. Army Medical Museum, Washington. Discussed by Drs. Dwight and Minot. 18. "Delimitation of Abdominal Regions," by Dr. E. A. Balloch, Howard University, Washington. Read by the Secretary. 19. "The Need of Agreement in the Limits of the Abdominal Regions," by Dr Gerrish. The last two papers were discussed together by Drs. Dwight, Piersol, Kemp, Heitzmann, and Lamb.

Several motions were made in regard to the disposition of these two papers and the discussion thereon. It was finally decided that, with the consent of the authors, copies should be sent to the committee on this subect of the Anatomical Society of Great Britain and Ireland; and also to the committee of the German Society.

20. "Physical Characteristics of the Kootenay Indians of Southeastern British Columbia," by Prof. Alexander F. Chamberlain, Clark University, Worcester, Mass. Read by title. 21. "Series of Thirty-five Natural-size Photographs of Sections of Human Brain," with brief remarks, by Dr. I. S. Haynes, University of New York.

The following members were present during the meeting: Messrs. Allen, Cope, Dwight, Gerrish, Haynes, Heitzmann, Herrick, Kemp, Lamb, Minot, Osborn, Piersol, Roberts, Ryder, Spitzka, Wortman, and Wright.

CORRESPONDENCE.

A "CANCER-CURE."

To the Editor of THE MEDICAL NEWS,

SIR: An "old woman" remedy for carcinoma has come under my notice within the past few years. Generally these remedies are based on mere superstition and are valueless. I have been very much interested in this one lately, because the old lady with this has succeeded in curing two epitheliomas. I promised profound secrecy, and she told me the remedy. The preparation is as follows: The juice is expressed from a large quantity of wood-sorrel (oxalis acetosella); this is poured into a pewter plate, and the whole placed in the sun and allowed to remain about one week. At the end of this time it has evaporated to a solid mass. This mass is then scraped away, and a part is applied to the diseased surface. Great pain appears in about twelve hours, and a few hours later considerable swelling is developed; both continue for about four days. On the fifth day sloughing begins, and a mass of diseased tissue falls out in one piece; later smaller portions slough way, leaving a clean, healthy-looking ulcer, which rapidly heals.

The juice of the wood-sorrel contains free oxalic acid and acid potassium oxalate. These act on the lead and tin (of which the pewter is composed), forming oxalates of these respective metals. Oxalates of both lead and tin are strongly caustic, and when applied to carcinomatous tissue act, I suppose, in a similar manner as do the zinc and arsenic pastes. I simply bring the above facts before the profession as a matter which may justify investigation.

GEORGE WALKER, M.D.

YORKVILLE, S. C.

THE PREVENTIVE TREATMENT OF TETANUS.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of December 31, 1892, you publish a very interesting article on "The Preventive Treatment of Tetanus." The article in question is not only interesting, but logical and rational. However, I do not know whether or not Dr. T. W. Simmons, of Hagerstown, Md., wishes to claim originality or priority for his suggestion. It seems to me that such means must have occurred to any physician at all acquainted with the etiology of the disease, and I have no doubt but that many have made use of such means. Suffice it to say, that Dr. J. A. Tarkington and myself, who do the surgical work of the Beltimore and Ohio Railroad in this city, have both used such treatment in all of our cases of traumatism where we have had occasion to suspect even the possibility of the development of tetanus. This we have done for many months on exactly the same basis

that Dr. Simmons very properly lays down. In not a single case where such treatment was used did tetanus subsequently develop. We, however, lacking the olive-pointed syringe which Dr. Simmons suggests, made use of the ordinary hypodermatic syringe.

Sincerely,

CHARLES MILTON BUCHANAN, M.D.,
Professor of Chemistry, Toxicology, and Metallurgy, National University.

WASHINGTON, D. C., January 18, 1893.

REMOVAL OF THE VERMIFORM APPENDIX.

To the Editor of THE MEDICAL NEWS,

SIR: Kindly inform me through the next issue of your paper, *when* and by *whom* the operation for removal of the vermiform process was first performed in the United States, and *who* performed the second one?

MINNEAPOLIS, MINN., January 8, 1893.

[See THE MEDICAL NEWS, August 6, 1892, p. 153; November 5, 1892, p. 531.]

NEWS ITEMS.

The Eighty-seventh Annual Meeting of the Medical Society of the State of New York will be held at Albany, February 7th, 8th, and 9th.

The following provisional program has been arranged:

President's Inaugural Address.

"The Relation, in the Male and Female, of Genital Disease to Mental and Nervous Affections," by Landon Carter Gray, M.D.

"The Epileptic Interval; Its Phenomena and their Importance as a Guide to Treatment," by William Browning, M.D.

"Reflex Disturbances in the Causation of Epilepsy," by William C. Krauss, M.D.

"Mental Epilepsy," by J. Montgomery Mosher, M.D.

"The Development of Epilepsy after Traumatic Injury to the Skull," by B. Sachs, M.D.

"The Treatment of Uremic Convulsions," by R. C. M. Page, M.D.

"The Registration of Midwives," by J. L. Kortright, M.D.

The Relative Value of Certain Obstetrical Operations.

"General Review of the Operations to be Discussed," by Dr. Egbert H. Grandin.

"The Limitations of Embryotomy," by Dr. N. Clifton Edgar.

"The Limitations of the Cesarean Section," by Dr. Robert A. Murray.

"The Anatomical Limitations of Symphysiotomy," by Dr. J. E. Kelly.

"The Clinical Limitations of Symphysiotomy," by Dr. Charles Jewett.

General Discussion, to be participated in by Drs. E. P. Davis, H. A. Kelly, H. C. Coe, and Reynolds.

"Practical Antisepsis and Asepsis," with stereopticon demonstrations (by invitation), by Howard A. Kelly, M.D.

"Epitaphs from the Tombstones of Medical History," with stereopticon projections of many old and rare medical portraits, by Joseph H. Hunt, M.D.

The Management of Suppuration Complicating Tuberculous Disease of the Bones and Joints.

Papers by Drs. V. P. Gibney, Roswell Park, Henry Ling Taylor, and Louis A. Weigel.

The Present State of Knowledge as to Carcinoma.

"The Pathology of Carcinoma," by H. C. Coe, M.D.

"The Etiology of Carcinoma," by Roswell Park, M.D.

"The Value of Internal Medication in the Treatment of Carcinoma," by Jarvis S. Wright, M.D.

"The Results Obtainable from the Use of Anilin Products in Carcinoma," by Willy Meyer, M.D.

"Caustics in the Treatment of Carcinoma," by Daniel Lewis, M.D.

"The Knife in the Treatment of Carcinoma," by N. Jacobson, M.D.

Discussion to be opened by Dr. George R. Fowler, of Brooklyn.

"Tuberculous Epididymitis," by Herman Mynter, M.D.

Newer Methods of Diagnosis and Treatment of Stomach and Intestinal Diseases.

"The Practical Value of the Newer Methods of Examination in the Diseases of the Stomach, with a Consideration of the Indications Given for Diet and Treatment by such Examinations," by Henry L. Elsner, M.D.

"The Methods of Obtaining and Examining the Stomach Contents in Disease for Purposes of Diagnosis," by J. Fuhs, M.D.

"The Disturbances of the Motor Function of the Stomach; Their Diagnosis, Symptoms, and Treatment," by C. G. Stockton, M.D.

"The Physiological Effects of Electricity in the Stomach, the Indications for its Administration and Use in Gastric Disease, and the Methods of Using the Same," by Max. Einhorn, M.D.

Anniversary Address by the President in the Senate chamber:

The Evolution of the American Surgeon.

"Report of a Case of Severe Abdominal Injury Terminating in Recovery," by J. S. Cooley, M.D.

"The Treatment of Inguinal Hernia," by Alex. Dallas, M.D.

"Certain Types of Septicemia Resulting from Abortion," by Andrew F. Currier, M.D.

"Puerperal Sepsis, Its Prevention and Cure," by William W. Potter, M.D.

"Hoarseness," by W. Franklin Chappell, M.D.

"The Diagnosis and Nomenclature of Fevers," by Nelson G. Richmond, M.D.

"Congenital Opacities of the Lens," by William F. Mittendorf, M.D.

"Is Stoerk's Blennorrhea and Laryngitis Sicca One and the Same Disease," by W. Freudenthal, M.D.

State Medical Examinations in New Jersey.—It is officially announced that candidates applying, after the meeting of the State Board of Medical Examiners of New Jersey, to be held in July, 1893, for licenses to practise medicine in that State, will be examined on the following subjects

arranged in sections, as follows, viz.: Sec. 1. Materia Medica and Therapeutics. Sec. 2. Obstetrics and Gynecology. Sec. 3. Practice of Medicine (including diseases of the skin, nose, and throat). Sec. 4. Surgery (including surgical anatomy, and diseases of the eye, ear, and genito-urinary organs). Sec. 5. Anatomy. Sec. 6. Physiology. Sec. 7. Chemistry. Sec. 8. Histology, Pathology, and Bacteriology. Sec. 9. Hygiene and Medical Jurisprudence. Before a license will be issued candidates examined in the first class, *i. e.*, graduates of five years or more, shall obtain a total average of 80 per cent. Candidates examined in the second class, *i. e.*, graduates of less than five years, shall obtain a total average of 75 per cent., providing that in no one section shall the percentage be less than 33⅓ per cent.; in which case, however, should the total average percentage in all the other sections be above 75 per cent., the candidate may be immediately granted a second examination upon that section. Candidates examined in the third class, *i. e.*, non-graduates, who have attended three full courses of lectures in a reputable medical school, shall obtain a total average of 80 per cent.; and candidates taking their preliminary or final examination, shall obtain a total average of 80 per cent. at each of said examinations.

Swallowing a Razor.—There was much excitement in Paris some years ago over "l'homme à la fourchette," a man who had swallowed a fork, which was successfully removed by a somewhat elaborate operation. A still more remarkable case has this week been successfully treated at the Lincoln Hospital by gastrotomy. The following is a brief note which has been furnished to us of this remarkable and interesting case: A woman, aged sixty-nine, in a depressed condition of mind, was supposed to have swallowed a full-sized razor on December 13th. She was admitted into the County Hospital the same day. There were no symptoms, and the presence of the razor could not be determined till December 18th, when the end could be felt at the pylorus. On December 19th vomiting commenced, and Mr. Cant, surgeon to the hospital, operated, opening the abdomen by an incision in the median line; then feeling the razor, and bringing the stomach to the opening, he was able successfully to remove it. The wound in the stomach was doubly sutured, and the external wound closed. Thirty hours after the operation the temperature was normal, the bowels had acted naturally, and there was no unfavorable symptom. The razor, a large black bone-handled one, was somewhat acted upon by its six days' digestion.—*British Medical Journal*, No. 1669, p. 1401.

The Cincinnati College of Medicine and Surgery.—Dr. J. Trush has resigned the Chair of Theory and Practice of Medicine in consequence of ill health, and the vacancy thus created has been filled by the transfer of Dr. E. W. Mitchell from the Chair of Materia Medica and Therapeutics.

Dr. G. A. Fackler, Professor of Materia Medica and Therapeutics at the Women's Medical College of Cincinnati, has accepted the appointment to the vacancy created by the transfer of Dr. Mitchell.

Esmarch, the distinguished German surgeon, celebrated his seventieth birthday on January 9th.

The Fifth District Branch of the New York State Medical Association will hold its ninth annual meeting in Brooklyn May 23, 1893. Fellows that desire to read papers will please notify the Secretary, Dr. E. H. Squibb, P. O. Box, 760, Brooklyn.

The R. I. Medical Science Monthly is the name of a new journal published at Providence, which is intended to make "a monthly review of reform and progress in the medical sciences." Dr. J. Frederick Haller is the managing editor, and he will be assisted by a corps of associates.

Correction.—A paper in THE NEWS of December 10, 1892, on "Abdominal Pregnancy," by Dr. H. A. Coe, contains the statement that the patient whose case was reported "was transferred to an insane asylum, from which she was discharged three months later mentally sound," etc. Dr. Coe wishes us to state that he was misinformed in regard to the subsequent history of the patient, who is still in the asylum.

BOOKS AND PAMPHLETS RECEIVED.

The Soil and its Relation to Health. By Edward T. Nelson A.M., Ph.D. Pamphlet, 1892.

The Medical Properties of Bromo-lithia Water. By W. A. Dixon, M.D. Reprint, 1892.

World's Columbian Exposition. Department of Liberal Arts. Circular No. 9. The Bureau of Hygiene and Sanitation.

A Case of Brain-Tumor with High Grade of Choked Disc. Autopsy. By Lewis H. Taylor, M.D. Reprint, 1891.

Kentucky School of Medicine in the City of Louisville. Register of Students, 1892. Circular of Information, 1893.

A Case of Pneumonia Treated by Transfusion of Blood from a Convalescent Case. By W. E. Hughes, M.D., and W. S. Carter, M.D. Reprint, 1892.

Intestinal Obstructions: Diagnosis and Treatment. By Frederick Holme Wiggin, M.D. Reprint, 1892.

An Experimental Inquiry Concerning Elastic Constriction as a Hemostatic Measure. By Nicholas Senn, M.D., Ph.D. Reprint, 1892.

A Case of Hemorrhagic Pleurisy; Probably Primary Cancer. By Andrew J. Downes, M.D. Reprint, 1892.

Diseases of the Kidneys and Bladder. A Text-book for Students of Medicine. By W. F. McNutt, M.D., M.R.C.S. Edin., L.R.C.P. Edin. Philadelphia: J. B. Lippincott Company, 1892.

Address on Medical Education. By J. T. Jelks, M.D. Pamphlet. Little Rock, Ark.: Press Printing Company, 1892.

Transactions of the Washington Obstetrical and Gynecological Society. Vol. iii. New York: Press of Stettiner, Lambert & Co., 1892.

A Contribution to the Study of Cystic Kidney. By Ludwig Hektoen, M.D. Reprint, 1892.

Diseases of the Lungs, Heart, and Kidneys. By N. S. Davis, Jr., A.M., M.D. Philadelphia and London: The F. A. Davis Company, 1892.

Tuberculosis of Bones and Joints. By N. Senn, M.D., Ph.D. Philadelphia and London: The F. A. Davis Company, 1892.

Report of a Case of Multiple Sarcomata in an Infant. By Frederick A. Packard, M.D. Reprint, 1892.

A Case of Akromegaly, and Illustrations of Two Allied Conditions. By Frederick A. Packard, M.D. Reprint, 1892.

A Plea for Early Diagnosis in the Pelvic Diseases of Women. By B. F. Baer, M.D. Reprint, 1892.

Ueber das Koch'sche Heilverfahren gegen Tuberkulose. Eine kritische Studie. Von Prof. Mariano Semmola, in Neapel. Reprint. Wien, 1891.

ORIGINAL ARTICLES.

THE TREATMENT OF CHOLERA.

BY ROBERTS BARTHOLOW, M.D., LL.D.,
OF PHILADELPHIA.

PERSONAL experience during two epidemics of cholera will, I trust, be considered some justification for adding another to the numerous papers that have appeared on the subject of cholera. Unfortunately, it cannot be said that the lessons of experience have been fruitful in curative results, but they afford unmistakable indications as to the direction our efforts should take in the future, and they have settled opinions as to the practical value of many of the proposed remedies. Until Koch's discovery of the comma-bacillus there had been no scientific basis for the therapy; but even now, with all the aid afforded by this great fact, the problem of a cure for cholera remains unsolved. The mortality-rate continues nearly at the same level, and although the epidemics have lessened in severity, these facts only show that sanitation has done much, whilst therapy, if not impotent, has been at least unequal to its prescribed task.

The theory of a cholera-seizure, based on the existence and agency of a specific microbe, may be stated as follows:

The parasite, reaching the intestinal canal by any of the several channels of communication, finds there a suitable nidus, and undergoes pullulation, increasing enormously in numbers, and producing as a result of its vital activity a peculiar poison—a ptomaïne—and on the action of this morbid material depends the systemic symptoms as they successively arise. First, we have the evidences of a local irritation—the cholera-diarrhea—due to the presence and development of the bacillus on the surface of the mucous membrane. Next is the stage of systemic infection, due to the absorption of the ptomaïne, quickly followed by the algid state, and then, should reaction occur, a typhoid condition. An important chemical change also takes place, consisting for the most part in an increased alkalinity of the intestinal juices and of the blood. Coincidently with these alterations occurs an extraordinary change in the mucous membrane; its epithelial layer is detached more or less completely, and the basement membrane laid bare. The normal functions are necessarily abolished, and the transudation from the bloodvessels is enormously increased. This outward diffusion of the blood-serum makes the blood thick, and its movement in the vessels sluggish, and the blood-globules become so much changed in structure as to be unable to functionate.

Such is the "therapeutic diagnosis" on which we now base our measures for relief.

The first point is to arrest the preliminary diarrhea. There are three indications for the use of remedies: the presence of a parasite in process of pullulation; the excessive alkalinity; the diffusion of the blood-serum from the vessels into the intestinal canal.

Of all the remedies proposed for the arrest of the diarrhea, not one has done so much good, in the writer's experience, as sulphuric acid. It is usual, and generally best, to combine some opium with it, according to the formulæ given below.[1] Sulphuric acid is a germicide; it neutralizes the alkalinity of the intestinal canal, and promotes diffusion into instead of outward from the vessels. During past epidemics opium has had an important place as the principal, or the adjunct, or associated, remedy. The experience of the present epidemic is against the use of large doses of opium, because of the narcotism, and the paralytic state of the intestine thereby induced. On the other hand, small doses, especially for the control of the preliminary diarrhea, are quite indispensable. I find that amongst those who are against the free use of opium, is Rumpf,[2] whose observations were made in the New General Hospital at Hamburg during the present epidemic, and also the veteran Ziemssen.[3] Both, however, find small doses useful in certain conditions, amongst which the preliminary diarrhea is most important. So necessary is opium during the first stage that all the formulæ most popular during the past and present epidemics contained it. I may mention the preparation of Squibb, which is largely used now as formerly. This contains rhubarb, aromatics, and the deodorized tincture of opium. According to Meyer the

[1] R.—Acid. sulphuric. aromat. . . . . ℥v.
Tinct. opii deodorat. . . . . ℥ij.—M.
Sig.—From ten to twenty drops every hour or two in sufficient water.

R.—Acid. sulphuric. dil. . . . . ℥iij.
Tinct. opii camph. . . . . ℥xiij.—M.
Sig.—A teaspoonful every half-hour or hour in water.

[2] Deutsche med. Wochenschr., 1892, No. 39. Abstract in Centralblatt für die gesammte Therapie, November, 1892.

[3] Münch. med. Wochenschr., 1892, No. 41. Ibid., Dec. 1892.

prescription given below[1] was employed for a diaphoretic action, and for the diarrhea a decoction of rhatany, with tincture of cinnamon and tincture of opium. Ziemssen advises fifteen drops of the tincture of opium in infusion of chamomile as an enema, to restrain the diarrhea. In India, chlorodyne—the original nostrum—has had the first place as a remedy for all stages of the disease. This preparation contains two ingredients of especial value, namely, morphine and atropine. Also, pills of lead acetate and opium, of tannin, capsicum, and opium, of camphor and opium—with or without tannin and capsicum—were largely employed. Indeed, it is impossible to name the various combinations in which confidence was reposed—each physician having his special pill or mixture. I should mention, also, that homeopathy had its favorite remedy in Rubini's solution of camphor—a saturated solution in alcohol. Almost any of the various combinations of remedies proved equal to the arrest of the preliminary diarrhea, if administered early enough. The case was far different when systemic infection occurred.

During the existing epidemic the treatment of cholera-diarrhea has been attempted on a scientific basis, and various new remedies have been brought into use. The modern doctrine of antisepsis, and the discovery of the cholera-bacillus, have led to the employment of germicides, which are administered with the view to arrest the development and to destroy the product of the cholera-microbe. But conclusions drawn from the results of the treatment of cholera-diarrhea can be depended on only when bacteriologic examinations have shown the presence or absence of the cholera-bacillus. The severity of the diarrhea is not a means of differentiating, for it has been found that in very mild cases the bacillus may be present,[2] and in cholera morbus there may be all the symptoms of true cholera, without a single parasite in the intestinal canal. In the absence of a proper bacteriologic diagnosis, the curative action of any remedy cannot be determined.

The remedies from which the most has been expected were salol and creolin. From a theoretic standpoint nothing could be more appropriate than the action of salol, for this substance is supposed to pass through the stomach unchanged and to be separated into its constituent elements—salicylic acid and phenol, by the alkaline intestinal juices; but the practical outcome has not been so fortunate as its promoters hoped for and predicted. At the Moabit Hospital in Berlin,[1] and at the New General Hospital in Hamburg,[2] salol and creolin were found useless. From my observation of the effects of naphthalin in the various forms of diarrhea, I am inclined to believe that this remedy promises well. As under ordinary circumstances it affects the whole intestinal canal, deodorizes the stools, and restrains the peristaltic movements, it should under the different conditions of a true cholera-attack accomplish similar results. Naphthalin may be combined with bismuth and carbolic acid, and opium may enter into the combination, if necessary.[3]

The experience of the present epidemic is in harmony with that of preceding epidemics as regards the utility of calomel as a remedy for cholera, but on very different grounds. Now it is regarded as the most efficient of the antiseptic remedies. Formerly it was given in truly massive doses—from ℈j to ʒj—to arrest vomiting, to secure "a change in the secretions," and to bring about bilious evacuations; and it was also administered in small doses (from ½ gr. to 2 grs.) to arrest vomiting, to act on the liver, and to exert its specific action on the gums, for it was not uncommon to hear a practitioner say: "If only the gums were touched," the case would take on a different aspect.

Rumpf maintains the superiority of calomel as a remedy over all other remedies that have been used thus far in the treatment of cholera. Ziemssen, also, strongly advocates it, administered in somewhat larger doses—usually giving a large single dose (8 grs.) at the outset, and smaller doses at short intervals thereafter. At the Hamburg New Hospital the initial dose was 4 grs. and subsequently every two hours 0.02–0.05 grams[=⅓–¾ gr. nearly] (Rumpf.) The administration of the calomel was kept up during the first and second stages. Similar use was made of calomel at the Moabit Hospital, Berlin.

Enteroclysis has come into use during the present epidemic. The method of Cantani, who is the author of this expedient, consists in irrigating the intestine with a solution of tannic acid. His directions are to take from 5 to 10 or 20 grams [1¼ ʒ to 2½ ʒ or 5 ʒ] of tannic acid in from 1½ to 2 liters [1 to 2 quarts] of hot water or chamomile infusion, and to this add from 20 to 30 drops of laudanum, and suspend by means of gum arabic,

from 30 to 50 grams. The temperature should be from 38° to 40° C. [99° to 104° F.] With this the intestine is irrigated. A fountain syringe with a glass reservoir, properly sterilized, is a suitable apparatus for this purpose. Views differ as to the utility of this procedure. At Hamburg and Berlin it was found useless; but Ziemssen, probably on theoretic grounds, urges its use at all stages. It is difficult to understand how irrigation of the large intestine can modify a morbid process going on in the small intestine—for nothing is more certain than that an injected fluid does not pass beyond the ileo-cecal valve. It is not surprising, therefore, to learn that actual experience with this treatment is not in its favor, notwithstanding Ziemssen's ardent advocacy, and Cantani's sanguine expectations.

So long ago as 1834, *infusion* of salines into the veins was practised. It had been seen at this early period how much injury the enormous outpouring of serum must inflict on the constitution of the blood, and on the circulation, and during every epidemic since attempts have been made to arrest the algid stage by supplying fluid to the veins, with marvellous immediate effect, but without permanent results. The modern expedient is less complicated than the operation for transfusion as originally performed. Now a simple reservoir for containing the fluid, a flexible tube, and a needle-trocar for perforating the vein, suitably sterilized, are the instrumental means required. The saline solution most used is one containing sodium chlorid and sodium carbonate. Hayem's solution consists of common salt 5 [= ʒj and ʒv], Glauber's salt 10 [= ʒij and ʒij], distilled water, sterilized, 1 liter [= 1 quart]. Cantani's solution contains 4 [= ʒj] of sodium chlorid, and 3 [= 48 grains] of sodium carbonate in 1 liter [= 1 quart] of water. The ordinary salt solution, properly sterilized, and at the right temperature, suffices.

Cantani[1] proposed the subcutaneous infusion of a saline solution, as a substitute for the intra-venous method. The term *hypodermatoclysis* has been contrived to designate this procedure. The apparatus required for the performance of this method consists of a reservoir for the fluid, a flexible tube, and a hypodermatic needle. The axillary region, the buttocks, and the inter-scapulary and subscapular spaces are suitable sites for the infusion. To secure the admission of a sufficient quantity of fluid, the infusion may be allowed to continue for some time (Samuel's continuous method).

Saline infusion is also practised by introducing the fluid into the peritoneal cavity. The same apparatus as that used for the subcutaneous method may be employed for this operation. The experience with the peritoneal transfusion is very limited for the present epidemic, and it need not, therefore, be considered here.

Infusion of salines is adapted to the treatment of the algid stage, to supply a material to the blood—the serum—which has been lost.

If the immediate effects of the intra-venous infusion could be fixed in a permanent state, nothing could be more effective than this mode of treatment. Unfortunately, the immediate and astonishing improvement is not sustained for any considerable time; in most cases a repetition of the injection becomes necessary in a few hours; the improvement each time is less decided, and still shorter in duration, until finally the injection is without effect and profound and fatal collapse ensues. The mortality in cases treated by intra-venous infusion in the New General Hospital at Hamburg was, in a group of 103 cases, 87, the rate being therefore 84.5 per 100, thus showing but little influence over the results in cases of the algid stage.

As compared with hypodermatoclysis, the advantage, slight as it is, remains with intra-venous infusion. The remarkable change at once manifest in the condition of the patient when the route by the veins is pursued does not occur to nearly the same extent when the subcutaneous infusion is practised; the effect comes on more slowly, and the result, as shown in the mortality following these methods, does not favor hypodermatoclysis. Rumpf declares that the subcutaneous method is not nearly equal to the intra-venous infusion in the algid stage. Both modes of treatment were much employed in Hamburg. In the two hospitals—the New and the Old General Hospitals—the method of intra-venous infusion was more used, and in private practice throughout the city the subcutaneous, especially the continuous method of Samuel, because of the greater care and safety with which it is done, and no assistant being required. At the Moabit Hospital in Berlin, Dr. Guttmann preferred the subcutaneous infusion of salines, and at Koch's Institute the intra-venous method was the favorite.[1]

From these facts it is evident that a final decision has not been reached regarding the comparative value of these plans of treatment, but it seems to me nearly certain that in the algid stage, with fatal collapse imminent, it were better to resort to the intra-venous method. In private practice, hypodermatoclysis is preferred by most of the Hamburg physicians, because an assistant is not needed and the injection is entirely safe, although abscesses have resulted in some instances. The large amount of fluid considered necessary, which is forced under the skin, explains the mishap. Irrespective of this, and considered from the point of view of the results

[1] Russell: Lancet, December 3, 1892, p. 1268.

in blood-transfusion, it is my belief that the quantity of fluid passed into the veins by either mode is much too large, one liter [= one quart] being considered the minimum. Yet at the Hôpital Bonjean, Paris, as much as two liters were injected in twenty minutes, and without any ill result so far as reported.

A new method of treating cholera is the subcutaneous injection of Klebs's *anti-cholerin*, a toxic material obtained from cultures of the comma-bacillus, after the method of Koch. This was also tried at the New General Hospital at Hamburg, and is reported on by Dr. Manchot, who compares the results of its use with the statistics of the intra-venous method. Of 31 cases treated by anti-cholerin there were 21 deaths, the mortality being 67.7 per 100; whereas, of 103 cases (already given) treated by saline infusion, there were 87 deaths, the percentage being 84.5. It should be understood that these were cases of cholera already advanced to the algid stage.

As during the algid stage of cholera the temperature is subnormal, the surface is cold, and the breath cold, the application of artificial heat in the shape of bottles of hot water, hot bricks, etc., was usually practised in past epidemics. During the present epidemic hot baths have been made use of at the Hamburg hospitals. Winternitz[1] extols especially the use of cool sitz-baths and frictions of the body with towels wrung out in the water. In Hamburg, Berlin, and in Russia, but rarely in Paris, hot baths were held in high esteem during the algid stage. The temperature ranged from 38° to 40° C., or from 99° to 104° F. The immediate effect of the bath is to raise the warmth of the body and to increase the pulse-rate and the depth and frequency of the respiratory movements.

The treatment of the algid stage by the use of medicaments during the present epidemic does not differ materially from that of former epidemics. There are some new remedies, however, that deserve consideration. The soluble salts of caffein were much used in Paris subcutaneously, and it is said with benefit. The diuretic action of this agent, as well as its stimulating effect on the circulation, were the chief reasons for its employment. In the Paris epidemic, especially at the Hôpital Bonjean, injections of cocaine, in the dose of 3 cg. [= gr. ss] per day, were administered with excellent results. Rumpf found no benefit from nitro-glycerin, oil of camphor, and other respiratory stimulants. Trussewitch[2] advocates the use of nitro-glycerin—two drops of the centesimal solution at a time placed on the tongue—and the hypodermatic injection of ammonia. As the mucous membrane is desquamating, it were better, no doubt, to inject the nitro-glycerin or amyl nitrite beneath the skin, or administer the amyl nitrite by inhalation. From *a priori* considerations it would appear more useful to administer these agents after the operation of infusion by either mode—for there is apparently little utility in forcing the organs of circulation when the blood is so thickened.

For the cramps which ensue when the muscles are no longer supplied with blood, small doses of morphine subcutaneously are recommended by Rumpf and others. In the last epidemic preceding the present, chloral by hypodermatic injection was highly extolled by some observers. I have no doubt from my personal experience that it has great value, especially when combined with morphine and atropine. As the solubility of chloral is limited, ten grains at a time are all that can be given unless several punctures are made. The following is a suitable formula:

℞.—Chloral. hydrat. . . . . ℥iij.
Morphin. sulph. . . . . gr. j.
Atropin. sulph. . . . . gr. ¼.
Aquæ chloroformi } . . āā ℥ss.—M.
Aquæ }

Sig.—Twenty minims, repeated in ten minutes, and subsequently *pro re nata*.

It is usually better to give the chloral separately—ten grains dissolved in sufficient water—and the morphine and atropine together—from ⅛ to ¼ gr. of the morphine and from $\frac{1}{120}$ to $\frac{1}{60}$ gr. of atropine. The effect of chloral on the muscular cramp of cholera is highly satisfactory. The pain ceases at once, the pulse rises, and the breathing gains in depth and volume. The last case of cholera treated by me, and one of the most severe, seemed to be rescued from a fatal ending by chloral injections. In this case, with the coming on of the cramp, the pulse became imperceptible at the wrist, and the respiration almost ceased. When the action of the chloral was felt, the surface grew warmer and pulse and respiration became more active. As, however, morphine and atropine had been given, some share in the result must be ascribed to them.

There are many other methods of treatment of cholera, and various medicaments, to which I have not referred, but this paper has already gotten beyond the space it should occupy. There is, however, a practical point or two in regard to the dietetic management of the disease that I should not fail to mention. The attempt to feed a cholera-patient when the digestive tract is undergoing desquamation is worse than useless. Such a preparation as beef-tea is only harmful at any stage of the disease. A little cold milk or wine-whey may be given as the state of the stomach will permit. The profound depression that occurs in these cases is a constant

[1] Centralblatt für die gesammte Therapie; op. cit.

[2] Ibid., November, 1892; from the St. Petersburger Wochenschr., 1892, No. 36.

temptation to push the use of stimulants, and this practice is usually overdone. A moderate quantity of iced champagne, a little brandy in ice, may be given from time to time. Thirst is excessive, and the indulgence in water-drinking is likely to excite vomiting, but, as Rumpf says, the advantages due to the free use of water more than counterbalance the injury done by a renewal or an increase of the vomiting. Carbonic acid water may agree better than simple water, or such a mineral water as Apollinaris may prove less likely to disturb the stomach. As the renal function is suspended, or nearly so, and as during the typhoid stage the restoration of this function is of the first importance, the free use of diluents may prove in a high degree useful.

NEGLECT OF THE EARLY DIAGNOSIS AND TREATMENT OF PULMONARY TUBERCULOSIS.[1]

BY S. EDWIN SOLLY, M.D.,
COLORADO SPRINGS, COL.

THE great importance of the early diagnosis of pulmonary tuberculosis has been forced upon my attention by finding so many tuberculous patients seeking the climate of Colorado long after their chances of recovery in that or any other climate have gone by. Considering it a matter largely preventable, by the profession realizing more clearly the causes of the conditions that lead to this unnecessary and lamentable loss of life, I have analyzed the last one hundred cases of pulmonary tuberculosis that have presented themselves for examination.

This inquiry has nothing to do with the influence of climate at an altitude or elsewhere (and the cases that have been gathered in the last few months are not considered in any way as to the results of treatment), but was undertaken to find how far the early recognition of the disease and its treatment affected the condition in which the patient came under my observation.

After going carefully over the notes of each case I have made two classes. The *first class* includes those in whom the disease was diagnosticated and treated as soon as the symptoms, as described in the patient's history, showed the disease sufficiently developed to be recognized by any ordinary well-educated practitioner. By treatment as applied to this class is meant any means, hygienic, therapeutic, or climatic, that were seriously used—not that the treatment was necessarily of the best, but that the cases were taken in hand and the patient advised in a reasonable manner. The broad question of treatment or no treatment of the pulmonary tuberculosis is dealt with, and not its details or wisdom.

[1] Read before the Arapahoe County Medical Association, December 27, 1892.

The *second class* includes those in whom the history exhibits the fact that the disease was not diagnosticated or treated for a period varying from a few months to several years after the time that the real nature of the malady had clearly revealed itself. The hundred cases are not in any way selected, but are taken in the order of their examination, tracing back from the recent time when this inquiry was commenced, and were limited to one hundred simply on account of time and labor; but I believe that if an analysis of the notes of all of my first examinations during the past eighteen years, the period of my practice in this locality, were made, the main bearing of the facts would be found the same.

DIAGNOSIS AND TREATMENT were delayed in 52 per cent., while in 48 per cent. the disease was promptly recognized and treated. The total average of delay was two years.

SPUTUM-EXAMINATIONS had been made in only 42 of the 100 cases, and in 7 of these not until some time after the disease was well advanced; so that it may be said that in 65 per cent. this means of diagnosis was neglected when most valuable. Of the 48 cases in which the disease was recognized and treated early, the sputum-examinations were omitted in only 13, while in the 52 cases of delayed diagnosis only 7 examinations were made, and then too late to be of practical value.

STAGE OF THE DISEASE.—Of the 100 cases, 37 were in the first stage; 28 in the second, that is, softening had commenced; and 35 in the third, that of tuberculization, when cavities could be diagnosticated.

Of the first class, 23 were in the first stage; 11 were in the second stage; and 14 in the third stage.

Of the second class, 14 were in the first stage, 17 in the second, and 21 in the third; so that of those who were cared for early there were 48 per cent. in the first stage, while in the delayed class there were only 29 per cent. in the first stage when they came under my observation.

RESULTS.—It is demonstrated by the statistics set forth in my article on "Climate,"[1] that the proportion of cures among the cases in the first stage treated in high climates, such as Colorado and the Swiss Alps, is 62 per cent., while in the second and third stages, taken together, the average is only 15 per cent. These figures show how greatly the chances of recovery have been lessened by the delay.

FAMILY PREDISPOSITION.—In 50 of the 100 cases the patients showed a family predisposition to tuberculosis. In 141 cases that I have reported[2] the percentage was 58; Dr. Denison's 240 cases showed 51 per cent.; Dr. Fisk's 100 cases, 52 per cent.; Dr.

[1] System of Therapeutics, edited by H. A. Hare. Philadelphia: Lea Bros. & Co.

[2] Transactions Climatological Association, 1890.

Theodore Williams reported 44 per cent. among 141 cases, while in the 1000 cases collected by his father and himself the percentage was 48. These figures suggest that the percentage of these 100 cases now analyzed, viz., 50 per cent., is near the average.

In dealing with the question of family predisposition the degree of relationship is of importance; in these 100 cases, parents, grandparents, brothers, sisters, and two or more uncles or aunts, who had pulmonary tuberculosis, are considered as showing family predisposition. Family predisposition was found in 29 per cent. of the first class, while it was found in only 21 per cent. in the second class, viz.: those in whom there was delay. This fact tends to confirm the opinion that I expressed in connection with the 141 cases referred to, that the knowledge of an hereditary tendency makes the patients seek and receive earlier treatment, and also exhibit greater attention in following it out; consequently, better results are obtained than among the non-hereditary cases. In the class in which treatment was delayed the hereditary cases show that there were 29 per cent. in the first stage, while among the non-hereditary there were only 26 per cent.

The average delay among the hereditary cases was 2 years and 5 months, among the non-hereditary 1 year and 10 months. This fact suggests that the disease tends to run a more chronic course among the hereditary cases, which, if true, may be explained by the theory that the family predisposition acts often like vaccination or inoculation, in granting a modified protection, so that the disease is slower to advance. The slightly better results among the hereditary may also possibly be due to inheritance granting a greater power of resistance, as well as teaching greater caution to the individual possessing a family history of tuberculosis.

The whole question of family predisposition, however, requires much more analysis and discussion than the limits of the present article will allow, and its full consideration would lead us away from the more practical matter of how to secure earlier diagnosis and treatment of pulmonary tuberculosis. For instance, the late experiments of Héricourt and Richet[1] upon dogs, which indicate that inoculations with tubercle confer more or less immunity, bear upon the subject. Then, again, under cover of the title, family predisposition, we have two distinct possible causes, though they may be often, and are, perhaps, always more or less allied. These are the direct transmission of tubercle-bacilli through the placenta, or the milk, and the inheritance of a physique favorable to the reception and the growth of the bacilli.

[1] Gaz. Méd. de Paris, October 22, 1892.

If the family predisposition is shown in the parents, and possibly in the grandparents, assuming the tuberculosis to be latent in the parents, we might have direct transmission, with more or less inherited susceptibility of physique. On the other hand, if the family predisposition was shown only in uncles or aunts or brothers or sisters, a susceptible physique would appear to be the only cause through inheritance.

NATIVITY.—In 80 of the 100 cases the patients were natives of the United States; 20 were born in England. Fifty-five per cent. of the American cases showed a family predisposition, while it was exhibited in only 30 per cent. of the English cases.

From previous observations I am inclined to think that a similar proportion of hereditary cases will always be found among the English and Americans, though it requires a much wider analysis to confirm this opinion. In the first class, *i. e.*, those who received immediate treatment, the American hereditary cases were 70 per cent., the English 43 per cent., while the total proportion of Americans in the first class was only 44.5 per cent., and of the English the proportion was 70 per cent. These figures would indicate that among English tuberculous patients the disease receives earlier recognition and treatment; and this point is also brought out in my paper already mentioned, in which the results of treatment are also shown to be better among the English than among the Americans. All this tends to confirm the importance of early diagnosis and treatment.

DIAGNOSIS.—We now deal with what to many is as tedious as a twice-told tale—how to make a diagnosis of early pulmonary tuberculosis; for the handbooks of Da Costa, Vierordt, Fenwick, Tyson, and many others tell us well and clearly how to do this. But why is it not done? Ruling out the cases in which the physician is not consulted in time, or in which he is ignorant or deliberately indifferent, it appears to me, from inquiry into the beginnings of a large number of cases of pulmonary tuberculosis, that the chief reasons are as follows: Among many of the laity and a few of the profession there lingers the old idea that pulmonary tuberculosis is a hopeless disease, whereas of some 5000 cases treated in various parts of the world, including elevated regions, and many of them some years ago, when the treatment was inferior to that of the present day, about 47 per cent. of cures were in those who were in the first stage.[1] And I have no doubt that at the present time, with earlier diagnosis and wiser treatment, the showing would be better. As has been stated, those cases in the first stage that were treated in high climates show 62 per cent. of cures, while 87 per

[1] Article on "Climate," System of Therapeutics, edited by H. A. Hare, M.D. Philadelphia: Lea Bros. & Co.

cent. were benefited; so that I believe it quite reasonable to say that in early pulmonary tuberculosis the chances of recovery are at least equal, and the earlier the diagnosis is made the greater are the chances. The percentage among the averages alone, in which improvement takes place, is undoubtedly higher.

As these statistics include those very grave cases of acute tuberculosis, and those whose poor physique and other disabilities render their chances slight, the average of improvement is brought down considerably. One of the reasons why pulmonary tuberculosis was believed to be hopeless was that before Koch's great discovery a patient was not believed to have the disease until the consuming process was well advanced. We must remember how Niemeyer, writing of what he termed chronic catarrhal pneumonia, spoke of the danger of its becoming tuberculous, whereas now we know that tubercle either preceded the inflammation or was quickly engrafted on it, giving it its chronic character. Then the cases of limited tuberculosis, without marked inflammatory changes, which recovered were not considered tuberculous, and so, being eliminated from the count, did not help to lessen the average mortality from pulmonary tuberculosis. Again, the physician who makes such a diagnosis when the signs are slight is often considered an alarmist, and another is likely to be sought who will say pleasanter things. Besides this repugnance on the part of the physician to declare a patient to have a (supposed) well-nigh incurable disease, and the distaste on the part of the patient who feels comparatively well to believe such a declaration, there still linger among both physicians and their clients two great myths: first, that pulmonary tuberculosis is *necessarily* hereditary, and, second, that it *only* attacks those of weak physique, both of which fallacies statistics destroy. Again, it is often hard for the physician to get the patient to submit to a thorough examination when he seems, perhaps, to be so little ailing, and he is often unwilling to give proper compensation for the necessary time and skill to be expended.

It is so much easier and pleasanter for both parties that a simple prescription for a "cold" be given, that a short holiday be advised, and that it be said "you are all right," than that disturbance be created, that a lot of apparently irrelevant questions be asked, and that the physician be free of the suspicion, perhaps, of wanting to make a case.

It is not given to every practitioner to have the required experience or skill to become a refined auscultator; but he can collect the facts from simple questioning and observation, which, taken together, will seldom fail, if tuberculosis is present, to show him the "handwriting upon the wall."

The question is: How could the diagnosis have been made earlier, and much of the precious time while the disease was yet in the stage of tuberculization saved? Of course, there are cases in which no physician is consulted till the disease is developed; but far more often the tell-tale signs pass unheeded under the physician's very eyes. For instance, one of the most glaring and extremely frequent negligences is not to search into the cause of blood-spitting, to make little of it, and say: "Oh! it came from your throat." Now, bleeding from the throat is very rare, except in acute inflammation or grave affections, in which event the physician's care is also needed; occasionally it comes from the gums or nose, and rarely from the stomach, when other signs will reveal its origin; but an inspection is seldom made.

The lungs are frequently not examined, or only examined through the clothing, when the fine distinctions between the two sides, or the slight change in the character of the vesicular murmur, or the semi-paralyzed chest-expansion, are lost. Even when an examination is made by an experienced auscultator, the signs may be too slight to found a diagnosis upon, yet when coupled with some of the other symptoms, they put the patient at least under grave suspicion, and demand that the physician should watch for further developments. In the meantime let him induce the patient to at least observe the ordinary rules of health and refrain from any indiscretions.

There may be no cough or expectoration and no other signs in the chest, and yet a constantly rapid pulse, a slight rise in afternoon temperature, or a subnormal one before rising, a trifling dyspnea on going up stairs, a little decline in weight, some loss or capriciousness of appetite, or a tired feeling unusually early in the day, may tell the tale, and, in spite of the absence of local signs, are "confirmations strong as proofs of Holy Writ." There is no one of these indications alone to be trusted. For instance, though loss of weight is one of the most constant signs, it is sometimes absent, and owing to, perhaps, a cessation of work or better care of the health being taken at the time, there may be gain instead. In fact, there are cases in which there is very little, if any, constitutional disturbance, and yet pulmonary tuberculosis is established; but such cases generally have distinct local signs, being those in which the tuberculosis is grafted on a preceding pneumonia, bronchitis, or catarrh. In this event, however, there is more or less cough and expectoration, and the microscope will reveal the secret in the sputum.

Some acute affections, such as typhoid fever, may at the outset be mistaken for acute tuberculosis; but as in these conditions the patient should be

watched and taken care of, no harm is done by a short delay in the diagnosis.

If cough, without expectoration and with slight, if any, local or constitutional signs, has persisted, particularly if of a dry, hacking character, tuberculosis should be suspected—that is, of course, after the causes of reflex cough have been well looked into, such as a tickling palate, enlarged tonsils, or disordered stomach. If these do not reveal the cause, then it lies either in the lungs or in some other grave condition of reflex irritation, and the patient should still be watched and directed, not dismissed. When headache and lassitude are complained of in the afternoon or evening, the temperature should be taken; if elevated, the patient should be carefully watched, and before long the cause will be discovered. A chronic bronchitis, or a pneumonia, or a pleurisy that does not clear up should always be suspected, and the sputum examined. Night-sweats, however slight, are to be inquired into. The breathing should be tested by laying the hand lightly on the epigastrium, with watch in hand, while the patient is made to talk, so that his attention is occupied; if the number of respirations is not greater than, say, 22 per minute, the patient may be made to go rapidly up or down stairs, after which the examination is repeated. A red line on the gums next to the teeth, and curved nails or clubbed finger-ends, particularly when blue, are always suspicious. The Scotch say: "Many a mickle makes a muckle;" and so it is from the accumulation of these little signs that the grounds for diagnosis are obtained.

TREATMENT.—Concerning the general outlines of treatment: first, after studying the disease, observe the patient's habits of life, and wherein they are not only adverse to the cure of the particular malady but sin against the general laws of hygiene, and then as far as possible correct them. See first to the digestion, and then give all the nourishment that can be assimilated; keep your patient as much as possible in the air and sunshine; encourage moderate and regular exercise, but never of a sudden or violent character; let it be proportionate to his strength, and gradually increased; but it must be very limited when the heart is weak or there is fever, and should be abstained from when fever is present; have the skin kept active by daily washing or sponging, but beware of fatiguing or chilling ablutions; clothe in wool both day and night, and train him to bear cold; medicate for symptoms or on general tonic principles; and if so inclined, you may experiment cautiously with some of the alleged specifics, such as creasote, but I regard their claims as still *sub judice*, and only to be proved by comparative experiments on a large scale in hospitals. My experience inclines me to believe they are all of doubtful value as specifics, but I think patients often improve under special forms of treatment because of the interest and hope inspired when something is being done for them, and their attention is directed toward getting well, and perhaps more particularly because the physician is likely to see his patient more often and watch him more closely, and so give more heed to the details of his daily life, in the wise direction of which lies the secret of success far more than in any medication.

It must especially be remembered that all sorts and conditions of men may become tuberculous, and you must study the individual and his circumstances as well as the type and stage of the disease, before you can plan a rational and systematic scheme of treatment for him. All this enters particularly into the question of change of climate. The well-to-do, whose domestic ties permit it, are most safely advised to seek at once the climatic change best suited to their case, and where such luxuries as have become necessities to them can be obtained, providing that they are or can be brought into a condition to stand the change. There are many, however, who, on account of their circumstances, cannot leave home, and should not be forced to do so unless home-treatment is not succeeding. Hereditary cases should *always* be sent away. Cases arising where the conditions of life, except the climatic, are good indicate clearly the necessity of change. Cases following pneumonia, pleurisy, and bronchial catarrh, which are slow in clearing up, also should have change. In the hereditary the change must be permanent; in the second group often so; but there is a certain number of cases that have arisen under peculiarly unfavorable conditions of life, and in which removal would be a hardship, and which, if they can be placed under good hygienic conditions at home, instead of bad, can often be safely left, at all events, till some experience is gained of the tendencies of their case. Those also in whom the tuberculosis is not advanced or active, and whose depression of health appears due to digestion or other causes that can be treated at home, may remain and be watched for a time.

Often a change to a different house or soil or different surroundings, physical or social, will start a patient toward recovery, if conjoined with other wise measures. As to what climate should be sought must be decided not on the usual happy-go-lucky methods or from the results in a single case, but by studying the general principles of climatology, and then getting reliable information of the particular resort that is likely to be suitable. Climatology (of which the profession as a whole is grossly ignorant) is not the pure empiricism that many think, but is a science founded on natural laws, and strengthened by rational experience.

ULCER OF THE STOMACH.[1]

BY L. WOLFF, M.D.,

CLINICAL PROFESSOR OF MEDICINE, WOMEN'S MEDICAL COLLEGE OF PENNSYLVANIA; PHYSICIAN TO THE GERMAN HOSPITAL OF PHILADELPHIA; DEMONSTRATOR OF CHEMISTRY, JEFFERSON MEDICAL COLLEGE.

EROSIONS and ulcerations of the gastric mucous membrane often occur as a result of trauma, and, as was long ago observed, readily heal without presenting the characteristic symptoms of "ulcus ventriculi," also known as simple, round, chronic, peptic, corrosive, or perforating ulcer, according to its shape, extent, and the fancy of authors.

Cruveilhier (1829–1835) appears to have been the first to recognize it as an independent affection, and to define its pathologic character. The subject was further elaborated and brought to a clearer understanding by Rokitansky and Virchow, who explained it as depending on a disturbance of circulation, with necrotic changes in the tissues supplied by the affected vessels.

These views have, from time to time, undergone some modifications, so that now autodigestion of the stomach within a circumscribed area is accepted as the pathologic condition associated with the affection. This conception is based upon the assumption that under normal conditions the alkalinity of the circulating blood prevents autodigestion of the stomach, while with the cessation of the circulation after sudden death during the digestive process the stomach undergoes a greater or less self-digestion (gastromalacia.) Any disturbance of the circulation of the mucous membrane of the stomach, whether by hemorrhage into it or by embolic processes within its vessels, must therefore be regarded as a predisposing factor in the production of a peptic ulcer. The exciting element, as already stated, is generally considered to be the action of the digestive secretions on the area deprived of the circulating medium, which, both directly and by diffusion, maintains an alkalinity of the tissues not overcome by the ordinary amount of hydrochloric acid in the digestive fluids.[2]

The ulcer so formed is by no means always round, as an inappropriate designation might imply, but may be variously shaped. It has clean-cut edges, and, as a rule, a clean fundus. It is principally met with in patients between eighteen and thirty years of age, and is found more commonly in women than in men. It shows a tendency to extend in depth to a greater degree than in surface, and is often funnel-shaped. It is generally situated upon the posterior wall of the stomach, near the pylorus, and, as a rule, is solitary rather than multiple. Ulcers extending to the deeper layers of the stomach may give rise to perforation, which, if not followed by fatal peritonitis, may result in adhesions to neighboring viscera. I have recently observed such a case in which, at the post-mortem examination, extensive adhesions between stomach, liver, pancreas, and spleen were found.

One of the most characteristic and important complications of peptic ulcer is hemorrhage from eroded vessels, and the resulting hematemesis. This, in connection with the other symptoms, may be considered as almost pathognomonic.

The tendency of gastric ulcer is generally toward recovery. The resulting cicatrization may cause serious complications by stenosis of the pylorus, and consequent gastrectasis, or even irregular contractions of the viscus. A suggestion of importance is the possibility of subsequent malignant development in cicatrices.

By far the most important and gravest symptom is, without doubt, the excessive hemorrhage that at times occurs. Of forty-three cases of undoubted gastric ulcer that I have followed, both in my own practice, as well as in that of others, in no less than four did fatal hemorrhage result.

Hyperacidity is usually mentioned as an accompaniment of gastric ulcer, and considerable importance has been attached to it. It is true that in many cases the mechanical irritation of the eroded surface by the food causes increased peristalsis and hypersecretion; but in quite a number of cases that I have had the opportunity of examining with this end in view, I have found only normal amounts of hydrochloric acid after the usual test-meal, and it is to my mind doubtful whether the hyperacidity so often mentioned in connection with gastric ulcer is as common as it is made to appear. While gastric hyperacidity often produces intestinal indigestion and intestinal catarrhs, resulting in mal-assimilation, malnutrition, and anæmia, which in turn may cause disease of the vessels, and thus predispose to peptic ulcer, I have yet to find that hyperacidity is more common in patients with gastric ulcer than in other persons.

Among the symptoms most noticeable in connection with ulcer of the stomach, pain deserves first attention. It is true that cicatrices of ulcers have been found in stomachs of persons who have never been known to complain of gastric pain; nevertheless, the large majority of cases are brought to our notice by the circumscribed pain in the epigastrium, radiating to the back below the scapulæ. The pain is characterized by its paroxysmal occur-

[1] Read at a meeting of the J. Aitken Meigs Medical Society of Philadelphia.

[2] This is disputed by G. Bunge (Lehrbuch der physiologischen und pathologischen Chemie), who, while offering no other explanation than the resistance of the living cell, asks, in contradiction to the above, why the pancreas is not digested by its alkaline trypsin.

rence and its relation to the taking of food. Thus, coarse food or large meals may cause most distressing gastralgia, and even a moderate meal may give rise to burning pain, which is often accompanied or followed by great nervous anxiety and cardiac palpitation, so that the patient is compelled to loosen his clothing and assume the erect posture. Pressure in the pyloric region increases the pain materially, and may often lead to paroxysms of varying severity. Together with this, the patient feels nauseated, often vomits, complains of heartburn and acid eructations, which cease only with copious emesis of the acid contents of the stomach, generally brought on by the patient's own interference. The vomited matters may or may not contain bile, but they often contain blood in greater or less quantities.

The great diagnostic importance of hematemesis will be realized if we consider the statement that it takes place in from 40 per cent. to 50 per cent. of all cases of gastric ulcer. I think the diagnosis doubtful in cases in which blood was not vomited, and I consider these figures, therefore, unreliable, and the average as greater. When the hemorrhage is large, it may be followed by syncope, and certainly by nausea, and if frequently repeated the patient may sink from loss of blood, which may be expelled by the bowel as well as by the mouth. The dejecta, under such conditions, usually appear as a black, coherent mass, of soft consistence and tarry color, though unchanged blood may, in aggravated cases, be found therein. The ejecta are usually mixed with food, but may be pure blood, generally coagulated, dark, and often fetid, but never frothy, as in hemoptysis; nor is the ejection accompanied by the characteristic cough of the latter.

As hematemesis is met with in cirrhosis of the liver, malignant diseases of the stomach, toxic erosions, hemophilia, and may result from trauma from foreign bodies in the stomach, it is necessary to exclude these in basing a diagnosis of gastric ulcer on hemorrhage, principally or alone. As corroborative of peptic ulcer, in conjunctiom with other symptoms, may be considered the dyspepsia accompanying it. This is manifested by a capricious appetite or even anorexia, eructation and pyrosis, with the so-called "heartburn," which often leaves a sensation of acid acting on the teeth. Together with this, constipation is the rule, varied though at times with occasional diarrhea and the popularly so-call "bilious" spells, with frontal headache.

The chemical examination of the gastric secretions, which has to be conducted with extreme caution, shows, according to some authors, a hydrochloric hyperacidity of from 0.3 per cent. to 0.35 per cent., a finding however, with which, from my own observations, as already stated, I cannot agree. Thus I have found that many, if not one-half of the cases, show a normal acidity, or even occasionally a subacidity.

Measurement shows no ectasis and the motor functions are generally excellent and may be increased. The ectasis resulting from subsequent pyloric stenosis cannot be viewed as symptomatic of the acute affection, though hyperacidity itself may bring about pyloritis and consequent ectasis.

As symptomatic of ulcer and resulting from the copious hemorrhage must be mentioned the extreme anemia that frequently suggests malignancy. It is often difficult to differentiate this secondary anemia from that of the progressive and pernicious type. The recognition of carcinomatous conditions of the stomach, when associated with ulcer, is one of the most perplexing problems for the diagnostician. Fortunately, though the association does exist at times, it is rare. Thus, in a case under my care, the symptoms were those of ulcer alone, when, notwithstanding the fact that the patient had not arrived at the age when carcinoma is ordinarily suspected, it was found at the autopsy that malignant disease of the cicatrix was undoubtedly the fatal lesion.

The diagnosis of gastric ulcer cannot be made from any one symptom, but must be based upon the corroborative evidence furnished by the complexus of symptoms to which it gives rise. Thus the digestive disturbances and gastralgia, as well as the circumscribed pain on pressure in and below the right hypochondriac region, the paroxysmal character of the pain, principally after the ingestion of food, are sufficient to attract the attention of the diagnostician as suspicious of gastric ulcer. If, added to this, there is the characteristic hematemesis, the clinical picture may be considered to be complete. Though pain may be absent at times, the hematemesis alone, when other sources of hemorrhage can be safely excluded, may serve for purposes of diagnosis. The diagnosis cannot be considered as established when based on the pain in the epigastrium alone, and, in fact, no positive evidence may be had of the presence of ulcer unless the chain of symptoms is made complete by the occurrence of hematemesis.

Gastric ulcer must be differentiated from gastric carcinoma. It may be said that the age of the patient is important, ulcer being more common between the ages of eighteen and thirty, and carcinoma after forty. One may, however, be deceived, as in the case already quoted. Rapid emaciation, with cachexia, as well as the presence of tumescence in the right hypochondrium, bespeak carcinoma, although tumefaction may at times also be found with pyloritis resulting from ulcer, and may even be wanting in carcinoma situated on the greater curvature and posteriorly, as I have had occasion to observe. That a chronic affection of the stomach which continues

over a period of three years, and though accompanied with emaciation, but without cachexia and without a palpable tumor, may be viewed as resulting from chronic ulcer, can be accepted as a safe rule, but one which is not without exception. The presence of a more rapidly developing tumescence in the epigastrium may, however, always be considered as evidence of malignancy.

The prognosis of gastric ulcer may, in the main, be said to be favorable, though, as already pointed out, the occurrence of fatal hemorrhage and the complication of progressive anemia, as well as malignant complications, may bring about a moderate percentage of deaths. The proportion of deaths among the forty-three cases that I have followed corresponds with the general statistics recorded. The perforative ulcer offers very few chances, though it has been known to leave adhesions which in themselves may not prove fatal.

The treatment of gastric ulcer may be summed up in a very few words. The primary indication is physiologic rest. If we consider that the presence in the stomach of food and acid secretions stimulates peristalsis, and that peristalsis is adverse to the restorative process, the indications for the control of both are at once established. As an adjuvant to this end and of the greatest importance, is absolute rest in bed. This is necessary, not alone to limit the mobility of the viscus, but it serves the further purpose of preventing tissue-waste, when nutrition must necessarily be limited or inhibited altogether.

The rest of the treatment may be considered as dietetic and medicinal.

The dietetic management is of the greater importance. While absolute bodily rest is a factor not to be neglected, physiologic rest is best secured by withholding all food by the mouth, and the adoption of a system of rectal alimentation. This will be the better borne, as the bowels are usually torpid and constipated and the colon tolerates large quantities of food very well.

To make alimentary injections the flexible rectal tube should always be used, and then introduced beyond the sigmoid flexure. Before resorting to alimentary enemata, the colon should be well cleansed and emptied by a large clysma of tepid water. It is to be remembered that, though the colon is a powerful absorbing organ, it is not a digestive organ, and that all food introduced into it should be predigested. I have been in the habit of employing for this purpose the glucose syrup of the market. This I dilute with peptonized milk, to which is added a moderate quantity of peptonized beef-extract, or the so-called peptone powder offered by the manufacturing chemists. It is fortunate that these peptonized preparations contain little peptone and more albumose, for it is to the latter rather than to the former that we have to look to furnish nutritive albumin. It is a time-honored custom to add from twenty to forty drops of laudanum to such injections, so that they will be retained by the bowels. As opium and the opiates have probably but little local anesthetic effect, I have substituted for them half a grain of cocaine for that purpose, with the happiest results. Treated in this way, by giving two ounces of glucose with one ounce of prepared peptone powder in about four ounces of peptonized milk, together with half a grain of cocaine, about three or four times a day, I have seen patients thrive and even gain weight.

It is customary and it is recommended that in gastric ulcer milk be given in large quantities, and milk alone. In several cases so treated I have observed hard coagula of milk to be vomited, after great distress and with great retching, leading to copious hemorrhage. I should modify this method by giving only partially peptonized milk, which will be found not to coagulate on the addition of acids. To introduce milk into a certainly acid and sometimes hyperacid stomach seems to me a folly which is often dearly paid for. As a substitute for peptonized milk, buttermilk (though not as nutritious but more palatable) may be given, but in small quantities at a time. To vary this, home-made mutton-broths, prepared from stock as required, and into which one or two raw eggs are beaten, are to my mind, much more desirable and decidedly more palatable than the various beef-extracts often recommended. With the absence or diminution of pain after ingestion, this liquid may be supplanted by a little well-soaked cream-toast or milk-toast, a little finely-scraped meat (ham is preferred by some), some rice in milk, custards, or a very soft-boiled egg. If these are well borne, the diet may be gradually increased to stewed fowl, mashed potatoes, succulent vegetables, and progressively to ordinary light and full diet. Carbonated waters, champagnes, koumyss, are generally not well borne and are contra-indicated.

The medicinal treatment demands, by the indications, first of all, alkalies, evacuants, correctives, and measures adapted to meet the complications. Probably no remedy has greater repute in this affection than the salts of the waters of Carlsbad. These should be given in hot water, while the patient is fasting. To avoid nausea, the dissolved salts should be administered in broken doses only. While much is said in favor of the natural salts, I find the artificial product equally as efficient and therefore, sometimes, preferable. A teaspoonful of the latter generally suffices for the purpose of a mild laxative. To assure alkalinity, and neutralization of the acid secretions of the ulcerated surface,

nothing has served me so well as sodium bicarbonate in doses of from fifteen to twenty or even thirty grains, about from half an hour to one hour after the ingestion of food or liquids, and this may with advantage be combined with bismuth subnitrate. Calcium carbonate and also magnesia are recommended for this purpose, but, in my experience, nothing is so well tolerated by the stomach for any length of time as sodium bicarbonate.

To combat the nausea and vomiting, a pill containing extract of belladonna, gr. ⅛, and silver nitrate, gr. ½, may be used with advantage; the latter is said to exercise a curative influence on the ulcerated surface, and by being converted into an insoluble chlorid, diminishes or neutralizes the hydrochloric acid present in the stomach. Pain is best combated by means of subcutaneous injections of morphine. As these may, however, be too frequently called for and lead to a habit not easily broken off, I prefer a pill containing morphine sulphate, gr. ⅛; cocaine hydrochlorate, gr. ¼; extract of cannabis indica, gr. ½, given every three or four hours, after the ingestion of food or liquids. These analgesics may with advantage be supplemented by warm poultices or even warm Priessnitz applications to the epigastrium.

To meet the most serious complication, that of hemorrhage, gallic acid, internally, and ergotin or fluid extract of ergot, hypodermatically, may answer. Pieces of ice should be frequently swallowed. Absolute rest is the *sine qua non*. Should the hemorrhage persist in spite of these measures and assume alarming proportions, Monsel's solution, in doses of three or five drops in a wineglass of water, may be administered every quarter or half-hour. Oil of turpentine and the oil of Canada fleabane are often recommended as hemostatics, but my experience with them in this affection has not been encouraging. If the anemia has reached an alarming degree, and if cerebral anemia is apparent, injections of ether and camphor may be practised, followed, if necessary, by subcutaneous infusion of a sterilized solution containing 0.6 per cent. sodium chlorid, at a temperature of from about 100° to 103°. As much as a pint of this may be injected into the subclavicular spaces, from which they are absorbed with remarkable rapidity. For perforation, little can probable be done, excepting absolute rest and the exhibition of cardiac stimulants hypodermatically to combat shock, together with the narcotics necessary to arrest pain.

This brings me to the surgical aspect of the treatment. With the present vast advances in abdominal surgery, may we not look hopefully for good results from surgical interference, both in chronic ulceration as well as in uncontrollable hemorrhage? not to speak of the certainly indicated surgical procedure in perforation of the stomach. The good results of Loretta's operation in pyloric stenosis foreshadow a wide field of usefulness for its application to serious cases of peptic ulcer and its more serious complications.

THE PRESENT STATUS OF DRAINAGE IN SURGERY.[1]

BY A. M. CARTLEDGE, M.D.,
OF LOUISVILLE, KY.

THE title of this paper, while seeming to embrace the entire subject of surgical drainage, is intended to refer to the question of primary wound-drainage. Our present knowledge of the principles upon which success in the treatment of septic wounds is founded will not permit of even the dream that artificial drainage can ever be eliminated from our resources as a secondary measure in wound-therapeutics; hence secondary drainage or pus-drainage will not be discussed here.

Before the researches and work of Chassaignac, medical history gives us little accurate data as to the progress of drainage through the past ages. We are enabled to trace the principle of drainage in the work of our forefathers in surgery by a continual warfare, with first one and then another faction in the ascendency, as to the relative advantages of the open and closed method of wound-treatment, which was but the expression of a sentiment for or against primary wound-drainage. With limited exceptions, the efforts of older surgeons to establish primary drainage partook of the natural variety, content to accomplish their purpose by so shaping incisions as to facilitate discharge, or by the practice of a partial or complete open method of treatment. I say this was the method, with limited exceptions, for we do find mention of the introduction of pledgets of lint and gauze as a primary procedure, though the purpose and limitation of these measures were poorly understood. As a matter of fact, the prevailing idea was that they gave an exit to products of inflammation, and they were left in the wound long enough to provoke what it was intended to relieve. To the great discredit of some modern surgeons, traces of this combined primary and secondary drainage, or perversion of drainage, are still to be found at the present day.

Interesting and instructive as it would be to trace the great principle of drainage through the network of advances in past surgical progress, it is not of direct and practical importance enough for our present purpose. The subject of primary wound-drainage may be said to be under very active discussion at the present time. It is true the argument

[1] Read before the Southern Surgical and Gynecological Association.

is, in some respects, a subdued one, for men naturally hesitate to take sides against a measure which every surgeon recognizes has been second to none in saving human life; yet, within the past two years, and especially within the past twelve months, we have all seen in the journals and society reports long lists of operations, all with the ever-inserted line "Closed without drainage." Converse in private with almost any one of the authors of such a paper, and you will find him more bold, probably admitting that he believes the time has arrived in wound-treatment when primary drainage can be dispensed with entirely.

We all know that beneficial as drainage is, and has been to our art, yet it is not without its evils; that in its application we either introduce into wounds a foreign substance, or at least an objectionable material. Hence we hail such expressions as at least prophetic of the time when our ideal shall be attained; when the brilliancy and achievements of modern surgery shall have forever reduced the open wound to the benign conditions of a subcutaneous one. Again, in accounting for the facts contained in such assertions as those referred to, we attempt to explain by the different conditions that probably surrounded the work of such men; the nature of the operations performed must have been very different from that of those encountered by men doing a different line of work, or general surgery. In others such reports tend to create a feeling of dissatisfaction with their own work (a good feeling to have produced at times), probably mingled with the disagreeable thought that they are not in the front file.

After twenty-two years of the more or less scientific use of primary artificial drainage in open wounds, we are confronted with the question: Is drainage a necessity; if so, when, and what is the best method of practising it? The reply to the first part of our question involves a brief *résumé* of the principles upon which primary drainage is founded. Such drainage is intended to convey from cavities and recesses of wounds, blood and serum. When the physiologic time for this has expired, the function of primary drainage has ceased. This time, with rare exceptions, is fairly definite, and is between twenty-four and sixty hours. To wait longer is to encourage trouble by the maintenance of a disagreeable guest; to remove before the lapse of twenty-four hours is taking risks not warranted in the premises. When the surgical conditions are such as to give evidence that its work is accomplished, the drain should be removed.

Primary wound-secretion is justly accredited with being the nidus or soil upon and in which multiply and develop the noxious agents so inimical to healthy wound-repair; hence the limitation of its production, its sterilization or its removal by some channel from the wounded tissue becomes a surgical necessity based upon the soundest surgical science. If we secure a limitation in the production of serum, or its sterilization *in situ*, is the successful progress of a wound assured without drainage? As to the first, we answer unhesitatingly "Yes." The nature and extent of a wound, the character of tissue involved, or both, may be such that with careful aseptic precautions and thorough hemostasis, the production of serum is practically prevented—at least as a factor in disturbed repair; hence, drainage is not only superfluous, but detrimental. In the more extensive wounds, we have in the buried gut-suture a means of the greatest value in enabling us to dispense with drainage by obliterating spaces, securing compression and rest, and thus preventing pernicious collections of serum. If we ever expect to succeed in the successful and uniform closing of large amputation-wounds without drainage, I feel satisfied that it can only be accomplished by means of the deep buried suture, which obliterates the deeper parts of such wounds. Other means, while often successful, are not attended with the positive and uniform results that should characterize most modern surgical work. In this connection it may be added that the same principle of deep suture may often be carried out by greater attention to extraneous means of compression by gauze compresses, which, by compression from without, tend to obliterate internal spaces. As an accessory means of limiting serous exudation must be mentioned the necessity of a more general use of measures of immobilization in soft-tissue wounds, and thorough attention to systemic or alimentary drainage. Thus, when the production of serum can be limited, other things being equal, drainage may be dispensed with.

Secondly, Will the sterilization of serum *in situ* assure the progress of a wound without disturbance? Let us dwell upon this a moment, for in the elucidation of this point rests the chief answer to the question: "Can drainage be dispensed with?" To illustrate this point, we will suppose a wound under the following favorable conditions: Perfect sterilization of all tissue adjacent and in the lines of continuity; perfect sterilization of everything brought in contact with the wound; perfect hemostasis; perfect approximation of the skin and superficial structures, and perfect protective dressings. The only undesirable feature about such a hypothetic case as that stated is that there are deep spaces and pockets in which serum accumulates.

With all the aforestated favorable protective conditions, it is reasonable to suppose that this serum is as unoffending as in a subcutaneous wound. We grant that it may, indeed the probability is that it

will, if in sufficient quantity, mechanically excite such irritation as may bring into being two latent elements of disturbance. The first of these is to be regarded in the knowledge that no wounded tissue, once exposed to the air, other than that of the highest mountains, or mid-ocean, is perfectly free from contamination; it probably has lodged in it pus-forming microörganisms deposited by the air, yet in such limited quantity that if further ingress is excluded, and not too much and luxuriant soil provided for their development, the vital resistance of the tissues is able to take care of them. Again, it is not safe surgery to tempt the lonely microörganism in his occasional voyages around the blood-circuit, with large and fertile fields of even sterilized serum, pent up in tissues and cavities of the body. As practical surgeons, we should ever remember that the aspiration or drainage of a hydrops articuli or pleuritic effusion probably saves the patient from a future purulent accumulation, with all of its disastrous attendants. Then tension may, by irritation, convert an accumulation of serum into a dangerous wound-disturbance, calling into activity latent microörganisms which would otherwise have been disposed of by the tissues. Lastly, in this connection must not be forgotten the fact, that primary wound-secretion, though so protected as to be a barren soil for the growth of disturbing agents, may, by its mechanical effects, be fatal to the functional interests of certain wounded structures, notably the brain and cord.

To this, the first part of our query, and one that the idealist in surgery is almost answering in the affirmative, we say "No." I have not dwelt upon the greatly differing conditions that exist between the work of the specialist and that of the general surgeon, or, more properly, the conditions that confront us in accidental surgery in contradistinction to surgery of selection and timely preparation. These differences readily suggest themselves to the practical general surgeon who has to deal almost daily with contused and lacerated wounds, the result of machine or railroad accident, where gross dirt and foreign bodies constitute no small element in determining the necessity for drainage, if good results are to be expected.

The second part of our question: "When shall we drain?" has been anticipated pretty largely in the previous discussion of the necessity for drainage. A proper appreciation of the function of drainage; conditions which surround the wound and manner of infliction; the perfectness of our appliances, and the constitution of the patient will be the chief determining factors. The axiom in abdominal surgery, "When in doubt, drain," is a most excellent one in general surgical practice, unless, like some surgeons I have known in abdominal work, always doubting. Probably we shall best know when to drain by formulating rules when not to drain. If the deeper parts of a wound can be approximated; if pockets and recesses can be obliterated by suture or compression; if the conditions favor natural drainage, dispense with drains. The buried suture will eliminate in a scientific way more drainage-tubes than any measure we are now acquainted with.

How shall we drain? Shall it be by tubular or capillary means? With material of an absorbable kind, or material that can be removed from the wound after its function of drainage has been performed? To answer these questions, let us again think of the purposes of primary drainage, and we shall see that a failure upon the part of the profession to appreciate the best forms of drainage is due to the want of knowledge in its management. If the surgeon knows how to manage drainage when once established, he will not be long in discovering the best material, at least for his own use. As between tubular and capillary drains in other than wounds of cavities of the body, it seems the preference should always be given to those acting by capillarity. With a thorough appreciation of the time required for primary drainage, and a knowledge of how the fluids, blood and serum, escape from wounds, there does not seem a valid reason why rubber tubes or absorbable tubular drains should ever be used. Certainly, when possible, preference should be given to a material the removal of which does not excite disturbance in the wound; also to material that so closely approximates the tissues in its composition as to permit of its softening, liquefaction, and final absorption. Such a substance is found in catgut strands. In large wounds, with free secretion, six or eight threads of large gut, made to traverse the entire deep part of the wound, and projecting from both angles, will drain it more effectually and more certainly than a fenestrated rubber tube of one-third inch in diameter. If there is any difficulty from bowing or fixing just where wanted, the method of Mr. Chiene (in which the strands of gut are tied in a bundle by a strand around the middle, and these with a needle attached sewed into the bottom of the wound) may be practised. Such a drain does not become plugged by blood-clot, and by virtue of its capillary action it will decant fluids from the bottom of pockets when a tubular drain would not. It is painless, for it does not produce compression; it does not soften too soon—*i. e.*, before its function is fulfilled. No dressings have to be disturbed for its removal. It lessens the paraphernalia of the surgical outfit, and is thus an element of simplicity, which, in turn, is one of the greatest elements of safety in surgical practice. The same bottle may contain the materials with which you tie the bleeding vessel, make your drain, approximate the wounded

surfaces, and which you again use as buried suture to prevent drainage. The size of the gut used, as well as the number of strands, should be proportioned to the size of the wound to be drained.

If there is troublesome parenchymatous hemorrhage, or oozing from a large denuded surface, and it is desirable to combine drainage and hemostasis in the same measure, strips of iodoform-gauze form the best method of primary drainage. In all other surgery, with the exception of the cavities of the body, the catgut strands are to be preferred.

SUMMARY.

1. The principle of artificial drainage in surgery, while very ancient, was imperfectly understood, and was oftentimes as much a factor for evil as for good.

2. Though our knowledge of the principles that govern a healthy regeneration of wounded structures has greatly advanced, and our progress in wound-therapeutics has kept pace, we fail to appreciate how artificial drainage can be altogether dispensed with in surgical practice.

3. To lessen the use of artificial drainage it is necessary to thoroughly apply the principles of asepsis and antisepsis, combined with buried sutures, fixation, and alimentary or systemic drainage.

4. If for any reason the exudation of serum cannot be controlled, its removal by drainage is a safer surgical measure than any attempt at sterilization *in situ*.

5. The time required for primary drainage is from twenty-four to sixty hours; to wait longer is to encourage trouble; to remove sooner than twenty-four hours is to take unwarranted risks.

6. Capillary drainage is to be preferred to tubular drainage in wounds other than those of the large cavities. For this purpose absorbable material should be selected, catgut being the best.

7. When it is desirable to combine hemostasis and drainage in the same measure, the strips of iodoform-gauze, as recommended by Mikulicz, fulfil a most useful purpose.

8. When natural drainage can be utilized without producing unsightly cicatrices, artificial drainage should be dispensed with; when feasible, the two should be combined.

9. Wounds involving the brain and cord had best be drained, to avoid mechanical violence to the function of delicate structures by retained serum.

10. Necessity for artificial drainage will most often arise in wounds invading the large cavities; herein flexible, tubular, glass drains best meet the requirements, aided or not by materials acting by capillarity.

11. The method of secondary suture after primary wound-secretion is over, advised by Kocher, seems to possess no advantage over drains that have to be removed, and certainly is not to be compared in convenience, comfort, etc., with the patient, to absorbable capillary drains.

A Tribute to Villemin.—The Leconte Prize of $10,000 has been awarded to the heirs of the late Professor Villemin by the Paris Academy of Sciences, for his researches on the infectiousness of tuberculosis.

ORIGINAL LECTURES.

HYSTERICAL SINGULTUS.[1]

BY PROF. CHARLES G. STOCKTON,
PROFESSOR OF THE PRACTICE OF MEDICINE, BUFFALO UNIVERSITY.

THE patient, Bertha W., nineteen years of age, is an unmarried German girl, a servant, of good family history. She came to this country eighteen months ago. She had had no previous illness. Two weeks ago her brother died of diphtheria. She began feeling ill five days ago and commenced hiccoughing; this has been kept up continuously ever since, in spite of the remedies of three physicians who attended her before she entered the hospital. She has not vomited, nor has she eaten anything since admission, two days ago. There has been intense headache since the hiccough commenced. The bowels are habitually constipated. She was given a high enema, containing ten grains of ox-gall, and has had twice daily and twice each night high enemata of mistura asafetida, ℥vj. Morphine has been administered in doses of gr. ¼, increased to gr. ⅓, and repeated as soon as the hiccough would begin again. Last night she slept four or five hours without hiccoughing, but began again as soon as she awoke. To-day she has taken a little milk.

This affection is a form of neurosis, technically known as singultus. The elements of hysteria seem to be present, and, in the disturbed state of her nervous system, it is easy to understand that from the excitement of the serious illness and death of her brother, some manifestation of hysteria might be established. You will ask me if singultus is not always a nervous disturbance, and it will be well to discuss that question briefly before entering on a minute study of this case. Hiccough is not a cough; it is quite the opposite. In coughing there is a violent expulsive effort on the part of the lungs, with a sudden partial or complete closure of the glottis. Singultus is a sudden inspiration by a spasmodic contraction of the diaphragm, with partial or complete closure of the glottis, giving rise to a peculiar gulping sound. Undoubtedly at times the glottis closes completely with a sharp sound, while at other times it is partly closed. I think it is due to the varying tension of the vocal cords that we have the different degrees and qualities of the sound.

Leaving out of consideration the ultimate causes, let us study the method in which singultus is produced. The diaphragm is innervated by the phrenic nerve, which springs from the fourth and fifth cervical. It is a mixed nerve, having both motor and sensory fibers, and it receives branches from the sympathetic. After passing over the lung and through the mediastinum it spreads out over the diaphragm and communicates with the solar and splanchnic plexuses. It is open to influences in a variety of ways, both through the cerebro-spinal and the sympathetic systems.

Hiccough may be produced by spinal or central nervous diseases; it may occur in ascending myelitis, in an uncontrollable form and often being the last of the patient's symptoms. Cerebral irritation, as by a tumor, or irritation along the course of the nerve, by the pressure of medias-

[1] Delivered at the Buffalo General Hospital.

tinal tumors, abscesses, enlarged lymph-nodes, effusion in the pleural cavities or pericardium—any of these things may also cause singultus. Irritation of the esophagus may be communicated to the phrenic, and thus hiccough is frequently set up by the effort at swallowing dry substances. Diaphragmatic pleurisy or subdiaphragmatic abscess may also be attended by singultus. Gastric diseases, often mild forms of indigestion, may give rise to hiccough, on account of the communication of the phrenic with branches from the solar plexus, which supplies the stomach. As the innervation of the various abdominal organs is more or less connected, irritation of almost any of these organs may cause singultus. Finally, we may have hiccough entirely as a reflex from uterine disease, spinal irritation, disease of the urethra, etc., just as asthma may be produced from disease of the nose and other remote lesions.

Singultus frequently comes on in certain conditions of nervous excitability of the nervous system. Children are very prone to hiccough, and mothers are accustomed to overcome this symptom in babies by giving a teaspoonful of cold water, or a few grains of sugar, to stimulate a reflex by the act of swallowing. Almost any reflex spasm usually serves to stop a hiccough, for it is a curious fact that one spasm may be overcome by establishing another. The vegetative nerves are extremely active in children, and all reflex and spasmodic phenomena are more often seen in children than in adults, whose nervous systems should have become more composed and developed. When, from any cause, the nervous system becomes perverted and over-susceptible, then reflexes and spasmodic states are more easily developed. A man, for instance, who has overtaxed his nervous system by any form of dissipation has more easily excited reflexes, and you all know how common hiccough is in drunkards. Overwork, loss of sleep, long-continued watching or anxiety are also predisposing causes of this kind of nervous phenomena. Acute illness also greatly strains the nervous system, and any such reflex spasm as hiccoughing is more easily set up and is controlled with more difficulty than when it occurs in the healthy individual. Among the most common general condition that predisposes to hiccough is hysteria, and in such a case the hiccough may become a symptom of so great importance as to constitute essentially a disease.

Here we have a young German girl who has lived for several months amid unfamiliar scenes, and among people speaking a strange language, who has been excited and exhausted by the sickness and death of her brother. You can readily understand the predisposition to some form of spasmodic trouble. You can also understand how the hiccoughing once set up would tend to continue, and how it would wear out the patient's strength, and render nourishment difficult, if not imposible. By gradually weakening the heart, even hiccough may put an end to life, and the condition in this instance has been considered so serious by several physicians that, after doing their best to improve the girl's condition in her lodgings,they have sent her to the hospital, in order to have everything possible done for her.

While I have been talking you have noticed the continual hiccough. You may not have noticed that the color of her hands was improving, and now, on feeling her pulse, I find it has become stronger, probably because appearing before you has excited her and stimulated her circulation, and partially counteracted the effect of the morphine. A careful examination of the reflexes is impossible, as she holds the legs firmly, and is evidently too much excited to relax her muscles. At several points on the face, hands and feet there is insensibility to the prick of a pin. When she entered the hospital several anesthetic areas were noticed on the left side, and the left conjunctiva was also anesthetic.

The treatment should be directed to control the spasm, and meanwhile to control the hysteria. For the latter I do not think there is any one drug that will compare with asafetida for controlling the symptoms, or, in fact, the disease itself. In any case of hysteria I advise giving asafetida in large doses. The officinal five-grain pill is perfectly useless. The mixture, or milk, should be given by the mouth, an ounce every hour, extending the interval to two hours, when the effect is noticed, and gradually extending to an ounce every four hours. This treatment should be maintained for a month or more. If the patient cannot, or will not, take asafetida by the mouth, give it by the rectum. It is in this way that this patient is being treated, with the object of controlling both the symptom of singultus and the hysteria.

Meanwhile, we must insure her rest, even at the expense of giving her large doses of morphine. Nourishment must be pushed as far as possible, realizing the difficulty of doing so in persons partially under the influence of morphine, and especially when swallowing is as difficult as it is in this case. Alcoholic stimulants may also be given with benefit. If not succeeding with morphine, one may add atropine, $\frac{1}{100}$ grain doses. Sometimes camphor in large doses will control hiccough when other remedies fail. Amyl nitrite, nitroglycerin, chloroform, or ether, are sometimes efficient. Musk has been largely used, and has been said to be a specific for hiccough, but it is nothing of the kind. Few druggists keep it, on account of the expense, and it is likely to be sophisticated. From ten to thirty grains of good Siberian musk would cost ten or fifteen dollars, and to saturate the system thoroughly with it would be more expensive than the "bichlorid of gold" cure. It is a good medicine, but its success is by no means so phenomenal as the textbooks would lead us to think. Castor is also good in the same way as musk and valerian and others of the same class. Asafetida is just as good, is much less expensive, and is not so offensive to smell as musk.

There are other contrivances for the treatment of singultus aside from drugs and foods. Sir Morell Mackenzie has said that if sneezing can be established in a person suffering from hiccough, relief can be obtained. Yesterday I tried to make this girl sneeze, without success. Her nose was tickled, she was given snuff—and she understood snuffing thoroughly, and filled both nostrils well—but without effect. I dare say there is some way of making her sneeze, and before we are done with the treatment we shall try the experiment again. I have no doubt that if we could only make the patient sneeze we could temporarily control the hiccough in the same way that a mother controls it in her baby, by setting up a reflex swallowing by means of water or a little dry sugar. You may ask why I do not attempt choking the

girl by passing the stomach-tube. That might be worth while; but I doubt if it would control permanently such severe hiccough. Faradism may be tried, passing the current through the diaphragm, and causing a tonic spasm of that muscle, which would control the clonic spasm of hiccoughing, at least temporarily. Others have a way of making strong pressure over the diaphragm with the hands clasped just beneath the ensiform cartilage, or pushing the hands up under the ribs, or by compressing the chest with a rubber bandage. The alternate hot and cold douche may sometimes be used with good effect. The actual cautery or other powerful counter-irritation over the pit of the stomach may afford relief. But all these measures are not sufficient for extreme cases. About the only practical treatment, then, for them is to give some drug that will keep the patient still, and some other drug that will stimulate and support the nervous system while waiting for Nature to do that something which will control the spasm of the nerve.

CLINIC HELD ONE WEEK LATER.

Here is the patient who was presented to you last week with singultus. She now makes—for your benefit—a little motion suggesting hiccough, but this is the only evidence of the trouble that I have seen for several days. I suppose the suggestion of coming before you has been quite enough to develop it. The treatment has been the use of asafetida, and, instead of the morphine which I suggested to you, I changed to chloral the same day on which you saw the patient, because the effect of the morphine given the night before the clinic had not been pronounced. At the suggestion of Prof. Cary, a little measure has been used which has stopped the spasm temporarily on more than one occasion: this was the injection of ice-water in the region of the diaphragm.

BRACHIAL PALSY FROM FRACTURE OF THE CLAVICLE—ISCHIO-RECTAL ABSCESS.[1]

By THOMAS H. MANLEY, M.D.,
OF NEW YORK.

The first case to be operated on is one of an unusual description, interesting in many important particulars.

The history is briefly this: The patient always enjoyed good health until two months previously, when, while on a debauch, he sustained a fall on his left shoulder, and immediately noticed that the left arm was powerless. Believing that he had a severe injury, his friends brought him to the out-door department of Harlem Hospital, where it was discovered that he had a fracture of the clavicle near its acromial extremity. The fracture was adjusted, and the man was told to come in again, after some days; but he failed to return as requested, though he put in an appearance after six weeks, when the arm related to the fractured bone was found entirely paralyzed. He said that the day after his shoulder was dressed he tore away the bandages and went to work, and had little inconvenience for four weeks, when the arm commenced to be painful and weak, and, in a while, was entirely helpless.

[1] Clinical lecture delivered at Harlem Hospital, New York.

Now, the question arises, What is the nature of the paralysis? Is it central or peripheral, primary or traumatic? The first proposition may, for many clear and obvious reasons, be readily eliminated. Bearing in mind the fact that the treatment of the fracture was totally neglected, its situation, the marked displacement of the fragments, with the large mass of osseous proliferation and callus, it is clearly evident that the marked muscular atrophy and motor palsy are wholly attributable to mechanical pressure—a condition not unlike what we may see in cases of osteo-sarcoma springing from the upper free surface of the first rib, at the part over which pass the neural and vascular supplies to the arm. We have, then, a compression of the tubular structures and nerves by excessive formation of a vicious callus.

The cause of the trouble being apparent, the next question that arises is, How shall it be dealt with? In the present instance, as the extent of deformity is so great and as the trophic changes in the soft parts are so marked, the rationale of treatment is clear, viz.: cut down, chisel away the excess of callus, re-fracture the bone with an osteotome, and so adjust the fragments as to aid in the full functional restoration of the shoulder and remove all pressure.

Though the indications are clear for surgical interference, their execution is full of difficulty and danger. When it is borne in mind that at this point the inferior surface of the clavicle is practically a part of the superior and anterior boundary of the pleural cavity; that the bone lies immediately over the brachial plexus and the subclavian artery and vein, it is at once apparent that we must proceed with skill and caution, so as not to infect the pleural cavity or wound those great blood-trunks which, in this situation, closely hug the bone.

I intend to make a long free incision over the long axis of the bone, and by keeping close to the new bone-formation, after stripping away the insertions of the subclavius and pectoralis major, avoid inflicting damage upon adjacent parts. This having been accomplished, with a sharp, strong, osteotome the callus is excised, when the sharply-cutting convex ends of the united fragments are raised on a strong periosteum-elevator, sawed in two with a metacarpal saw, and sufficiently gnawed away with the rongeur to permit the ends to come together without strain or pressure. Now, a small wire suture is passed through the ends of the bone and fixed. The wound is closed without drainage.

The next patient is a young man of twenty-three years, with a tuberculous history, who is suffering from an ischio-rectal abscess.

This young man has been sent for treatment for piles: it is quite certain that there is some type of hemorrhoidal disease, but the general condition and local examination betokens something else. The patient has a large pus-accumulation, evidently of hemorrhoidal origin; the pile first becoming inflamed, then suppurative changes occurring and making their way through the walls of the bowel into the loose cellular tissues. In connection with operative procedures, the question arises as to how we should deal with these cases to the best advantage.

Should we be content with making a free incision and draining away the pus, or should we search for the opening in the rectum, and do, at one sitting, the combined

operation of evacuating the pus and splitting up the fistula? Much may be said for and against either procedure, but my preference in all cases of this kind is to be content with making an opening into the abscess. My reasons for this are that if the internal opening is high up, by division of both sphincters incontinence of feces may follow, or, what is very common in cases of strumous rectal fistulæ after operation, we may have great difficulty in healing the wound made, and it scarcely closes before another fistula appears. And I may say here that, should an anal fistula follow, I shall, with him, pursue my common rule with this class of cases—viz., if it gives rise to no pain or serious inconvenience, I shall let it alone.

P. S.—The operation in the first of the above cases was followed by the most satisfactory results. There was no surgical fever, no hemorrhage, no pleurisy, and in two weeks the patient left the hospital with full functional restoration in the arm and hand.

The patient with the abscess left the hospital with a small painless anal fistula.

CLINICAL MEMORANDA.

SYMPHYSIOTOMY IN PRIVATE PRACTICE.

BY HARRY McKENNAN, M.D.,
OF PARIS, ILL.

THE report of the following case of symphysiotomy is of interest from the fact that the operation is a new one to American obstetricians (this being the fourth recorded case in America), and because it occurred in private practice, in a small house of two dingy rooms, where there were no conveniences and but few necessary comforts.

Mrs. S., thirty-one years old, 4½ feet tall, of an average weight of 102 pounds, and with an antero-posterior pelvic diameter of 2¾ inches, had been delivered twice previously, and each time of a dead child, craniotomy having been necessary.

On the night of December 15, 1892, at about 11 o'clock, the patient began to have labor-pains. Eight hours afterward I was called. Upon examination I found the os well dilated, the membranes ruptured, and the cord prolapsed. The head could be reached by my finger, but on account of the small pelvic inlet, it could not be made to engage. The cord was returned, and Dr. Z. T. Baum (who had been present at her two previous confinements) was called. Symphysiotomy was decided upon, and Dr. W. H. Ten Broek was asked to assist in the operation. At 10.30 A.M. the pubes was shaved, and the parts thoroughly washed, first with soap and water, and afterward with a solution of mercuric chlorid 1 to 2000. Chloroform was given and the operation was begun.

An incision was made over the symphysis, and the attachments of the recti muscles were divided sufficiently to allow my forefinger to pass under the symphysis. A strong probe-pointed bistoury was then introduced, but, to my disappointment, I found that the union between the pubic bones was too firm to be overcome by such a knife; and I was compelled to lay it aside, and make use of a narrow probe-pointed metacarpal saw. (I had ordered of the instrument-maker a Galbiati's knife, but it reached me by mail an hour after the operation had been completed.) The saw worked nicely, however, the point being well guarded by my finger, while an assistant with a catheter in the urethra pressed the soft parts back and to one side. What little débris was caused by the saw-teeth was carefully washed away, and the wound was covered with iodoform-gauze. By the time the symphysis was cut through the child had so changed in position that the head lay in the right iliac fossa, with the left arm protruding its full length through the os, and the cord prolapsed. The cord was returned, the arm replaced, and cephalic version was performed.

Version was easily accomplished, owing to the impossibility of the body or head of the child engaging in the superior strait. As soon as the head was again in position, the forceps was applied, and I then asked Dr. Baum to deliver, which he did very rapidly on account of the prolapsed cord, the pubic bones gaping about three inches. The wound was then thoroughly cleansed with solution of mercuric chlorid 1 to 3000, stitched with silk, and covered with iodoform-gauze held in place by adhesive strips. The hips were bound firmly with a roller. A vaginal douche of mercuric chlorid, 1 to 2000, was given. The knees were tied together, and a tight binder applied. The gauze dressing was accidentally removed by the patient as she was recovering from the anesthesia, and I dusted over the wound boric acid powder one-quarter of an inch in depth, and covered this with a large piece of surgeon's silk isinglass plaster. This last dressing I greatly prefer, as it has the advantage of not only protecting the wound, but of being more easily kept in place, and also of being semi-transparent.

The operation occupied one hour, but could have been accomplished in one-half the time had the saw been used in the beginning, instead of the bistoury. Thirty-six hours after the operation the patient's temperature rose to 101°, but after thoroughly cleansing the parturient tract, and providing her with a more comfortable bed, her fever disappeared, and the temperature has never since been above 99°. A vaginal injection of mercuric chlorid, 1 to 2000, was given once daily until the lochial discharge ceased. The stitches were removed on the fifth day, when the wound was found to be thoroughly healed.

Nearly two weeks elapsed before involution had taken place sufficiently to allow the womb to return to the contracted pelvis. In twenty-eight days the woman was allowed to get up. She suffered no inconvenience, except the general weakness caused by her long confinement in bed. She is now able to be about the house, and expresses herself as feeling as well as ever.

The child, which weighed eight pounds at birth, is well and healthy.

I had never entertained a friendly feeling toward the operation of symphysiotomy until I read the valuable paper of Professor Barton Cooke Hirst,[1] presented to the Philadelphia County Medical Society in October last. The thanks of the profession are due Professor Hirst for making public his admirable paper.

It seems to me that in this country, symphysiotomy should supplant craniotomy, and in private practice it has the advantage over the Cesarean section of being

[1] MEDICAL NEWS, October 15, 1892, p. 431.

less formidable, and offering the mother an equal, if not a better chance for recovery.

OVARIAN CYST WITH INTERNAL HEMORRHAGE; OPERATION; RECOVERY.

By H. C. MASLAND, M.D.,
of Philadelphia.

The case here reported came under my observation while resident physician at the Wilkes-Barre City Hospital. Because of its complication it seems worthy of mention among reported cases of ovariotomy. I am indebted to Dr. J. A. Murphy for his courtesy in permitting this publication.

Mrs. M., thirty-seven years old, has borne ten children. She states that she has had fever after the birth of four of them. Following the birth of her last child, four months before admission to the hospital, she had chills and fever. Since the birth of the last child she has noticed herself gradually growing larger, without troublesome symptoms, till Friday evening, January 22, 1892, when she was seized with sharp pain in the left side, spreading thence over the abdomen. There was at the same time marked prostration, irritable stomach, chills, fever, extreme thirst. There was a feeling of great distention and a sensation as though something had ruptured.

The woman was admitted to the hospital on the following Monday. On admission she complained of sharp pain in the left side. The breathing was rapid and labored; the pulse frequent and weak; the temperature 101°. There was excessive thirst, but nothing could be retained by the stomach.

On the following day abdominal section was performed by Dr. Murphy. The tumor proved to be, as diagnosticated, a large ovarian cyst. There were numerous slight adhesions to the abdominal wall that were easily broken up. The pedicle was small and was ligated with comparative ease. The operation was performed with the strictest aseptic precautions. No drainage-tube was used.

The ether was administered for an hour and fifteen minutes. Prior to its administration a hypodermatic injection of strychnine was given. Whiskey and digitalis were each injected once during the course of the operation.

At the commencement of the anesthetization the pulse was 146 in the minute, the temperature 102°. Throughout the operation the general condition, if at all changed, was somewhat improved. At the close of the operation the temperature was 101.6°, the pulse 128.

The tumor weighed about thirty pounds. On examination, its inner surface was found covered with a layer of coagulated blood. This hemorrhage into the sac, it was believed, accounted for the acute symptoms of the previous Friday evening.

The patient reacted well and progressed steadily to perfect health. The bowels, inclined to be constipated, moved freely after the administration of salts. Catheterization was also necessary for a few days following the operation.

Union took place by primary intention. The patient was discharged eighteen days after the operation.

This case was especially interesting to those who witnessed the operation because of the internal hemorrhage. Prof. Goodell[1] speaks of hemorrhage within the sac as an occasional accident, with consequent septicemia if not immediately operated upon, operation being the sole chance of life.

In this case the clot was well formed, had undergone contraction and was firmly adherent to the cyst-wall. The serum of the blood was intimately mixed with the ovarian fluid. There was no evidence of any destructive change in progress.

In this case it appeared that had the circumstances been favorable, the clot might have gone on to complete organization.

2027 Allegheny Avenue.

MEDICAL PROGRESS.

Cerebral Anthrax.—Merkel (*Münchener medicin. Wochenschr.*, 1892, No. 47, p. 840) has reported the case of a whitewasher, twenty-two years old, who for three or four days had behaved peculiarly and had vomiting and diarrhea, with pain in the sacral region. The man complained of a feeling of fatigue and of vertigo, and presented a lead-line at the margin of the gums. At the lower part of the posterior aspect of the right chest there was a small area of impaired percussion-resonance, with fine moist râles. The man fainted during the examination, and was evidently quite ill. The temperature was 103.1°. On the following morning the patient became unconscious. In the afternoon he had several epileptiform seizures, and the breathing assumed the Cheyne-Stokes character. In the right eye-ground the margins of the papilla were obscure, and there was a slight staphyloma. The urine was passed involuntarily; a small quantity, obtained by means of the catheter, contained hyaline and granular casts and vesical epithelium. The loss of consciousness persisted, until the man died in the night of the same day. At the post-mortem examination a packet of glands, about as large as a small apple, was found in the posterior mediastinum. The mass was surrounded by a fibrous capsule, and on section was seen to include a number of nodules of various size, each provided with its own capsule. The spleen was considerably enlarged; its capsule shrunken. The stomach was injected and presented numerous small superficial hemorrhages. The intestines were likewise injected, and the solitary follicles were slightly swollen. The dura mater was pale and translucent. The pia was quite injected, easily removable, and somewhat turbid; beneath the pia the sulci in various situations were filled with a gelatinous material; the convolutions were somewhat flattened. The ventricles were slightly dilated and contained a few ounces of clear serous fluid. On section, the cortical tissue appeared pale, though in places containing numerous small red points, apparently hemorrhagic. Sections of the ganglia and of the cerebellum disclosed the presence of similar points, which occupied especially the gray matter. Upon agar inoculated with fluid expressed from the spleen, anthrax-bacilli developed. Similar organisms were found in sections of the hardened brain, spleen,

[1] Lessons in Gynecology, 3d ed., p. 432.

and mass of glands from the mediastinum. In the spleen and mediastinal glands the bacilli were irregularly distributed among the cells, and only in few places in large numbers. In the brain most of the vessels were filled with bacilli. In some places the organisms had escaped from the vessels into the surrounding tissues; in other places they lay in the midst of extravasations of blood. The source of infection could not be determined. It was only known that the patient had in his daily work handled bristle brushes. The thought is suggested that the germs may have entered by the respiratory or gastro-intestinal tract.

Hemorrhagic Goiter in the Course of Pregnancy.—ESTOR and CADILHAC (*Nouv. Montpellier Médical*, 1892, No. 6, p. 758) have reported the case of a woman, thirty years old, in the sixth month of pregnancy, from the beginning of which an enlargement of the neck which had been present for eight or nine years, slowly and progressively increasing in size, had undergone great increase. For nine days there had been constant hemorrhage from two small ulcerated points on the most prominent part of the tumor. The bleeding had at first been rather profuse, but subsequently it became much less, but continuous. The woman had become quite weak, anemic, and cachectic, and complained of vertigo and palpitation of the heart. The sounds of the heart were duplicated, and at the apex a faint blowing murmur could be heard. From the size of the tumor, its irregularity of surface and consistence, the condition and appearance of the patient, and all of the attendant circumstances, it was thought that the condition was one of telangiectatic sarcoma of the thyroid gland, but the subsequent course of the case proved the diagnosis to be incorrect. It was determined to remove the gland. The operation was an extremely bloody one, and the mass was removed only in part. Three days after the operation the woman aborted with a six months' child. The wound united rather tardily, but the patient ultimately made a satisfactory recovery. Ten months after the operation she was perfectly well.

A Complicated Labor.—KOETTNITZ (*Deutsche medicin. Wochenschr.*, 1892, No. 45, p. 1012) has reported the case of a woman, forty-three years old, one of a family of twelve, whose mother had once borne twins, who had herself twice borne twins, and was pregnant for the eleventh time. In the labor one child had been delivered by a midwife, but the further progress of the case was checked by the presentation of two feet, one hand, and a portion of a head, so that the possibility of triplets was considered. All efforts to turn were futile. After the child had died, craniotomy was performed. With some difficulty the second child was extracted. It appeared that the child must have presented by the feet, the lower extremities being extended and the pelvis high up in the uterus. The woman made a good recovery.

The Predisposition to Tuberculosis.—FERMI and SALSANO (*Centralbl. f. Bakteriol. u. Parasitenk.*, xii, 21, p. 750) have made an experimental study to determine the conditions that increase the predisposition to tuberculosis, as well as those that increase the virulence of the tubercle-bacilli. They found that by exposure for several weeks to a temperature of from 91° to 95°, especially if the surrounding air were saturated with moisture; further, by the injection of grape-sugar and lactic acid, guinea-pigs and mice could be rendered susceptible to the tuberculosis of fowls, and mice to the tuberculosis of mammals. The tuberculosis of fowls could be made virulent for guinea-pigs by repeated inoculation of animals rendered susceptible.

THERAPEUTIC NOTES.

Salol Subcutaneously in the Treatment of Pulmonary Tuberculosis.—GROSSI (*Rif. Med.*, Oct. 31; *Brit. Med. Journ.*, No. 1665, Epitome p. 87) has reported the employment subcutaneously of salol in eleven cases of pulmonary tuberculosis at various stages. The drug was dissolved in oil of sweet almonds in the proportion of one to three. At first the equivalent of twenty-five grains of salol was injected daily; after a little while the dose was increased by twelve and a half grains every second day until seventy-five grains were being injected in three equal doses. The injections were made in the gluteal region, and caused neither pain nor reaction; when swelling occurred the injections were for a time omitted. Cod-liver oil was employed as an excipient, but was abandoned because it gave rise to local inflammation, which, however, it is thought may have been due to impurity of the oil. In all of the cases but one, in which the disease was far advanced, the treatment was followed by good results; fever and night-sweats ceased, cough was relieved, the number of bacilli in the sputum diminished, the patients gained strength, and the weight increased.

For Chancroids.—CAVAZZANI (*Giorn. Ital. della Malat. Vener. e della Pelle*, fasc. 2; *Monatsh. f. prakt. Derm.*, xv, 11, 1892, p. 586) recommends the following combination as a topical application in the treatment of chancroid:

℞.—Chloral. hydrat. . . . ℥ijss.
Camphoræ rosæ . . . ℥jss.
Glycerin. neutral. . . . ℥jss.—M.

S.—The camphor and the chloral are rubbed up in a mortar to a transparent fluid; then the glycerin is gradually added, and the whole is heated over a water-bath at a temperature of from 122° to 140°. The preparation should be recent. The application is made morning and evening by means of a glass rod, after the ulcer has been cleaned, and a covering of cotton is finally applied.

The Creasote-treatment of Pulmonary Tuberculosis—From the results obtained at the Hospital Moabit, at Berlin, from the employment of creasote in the treatment of pulmonary tuberculosis during a period of almost five years, ALBU (*Berliner klin. Wochenschr.*, 1892, No. 51, p. 1300) arrives at the conclusion that the agent exercises no direct influence upon the tuberculous process in the lungs, although it is admitted that it is a useful remedy in the symptomatic treatment of the disease—probably better than any other. In most cases it acts as a good expectorant; in some cases as a stomachic; as a rule, it appears to exercise a tonic influence. In a series of experimental investigations it was found that no change in the virulence of the sputum manifested itself in persons that were taking creasote in full doses.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 4, 1893.

THE DEGENERATION AND REGENERATION OF NERVES.

THE study of the changes that take place in a peripheral nerve, after severance of its connection with the nerve-centers, is one interesting alike to the physiologist, the neurologist, and the surgeon. The literature on the subject is voluminous, that of the experimental work alone dating back over 100 years; and there have always been wide differences of opinion with regard to the explanation of many of the processes, numerous points even yet remaining obscure. That the two ends of a divided nerve can unite was established early in the history of medicine, but with CRUIKSHANK and HAIGHTON, in 1795, began the study of the question of a return of function after union, and the histologic changes upon which such a return might depend.

It would take us too long to review at all carefully the results of the various experimenters. Suffice it to say, that it has been demonstrated that a spinal nerve can, after section, reunite and again become capable of performing its functions; and more, that the peripheral end of one spinal nerve can unite with the central end of another, and function return. It has not yet been proven, however, that a pure motor trunk can unite with a pure sensory trunk, with return of functional activity in the peripheral portion. The ingenious experiments of SCHIFF, REICHERT, PHILIPPEAU, and VULPIAN, on the lingual and hypoglossal, and on the vagus and hypoglossal nerves, seemed at first to be positive; but, as HEIDENHAIN and others have shown, the interpretations that they have given of their results cannot, on closer examination, be regarded as satisfactory.

With reference to the degenerative changes that occur after section there has been much discussion, and the view of WALLER that the peripheral portion of a nerve undergoes complete degeneration has been many times challenged. There is a certain amount of evidence, chiefly clinical it is true, in support of the statement that union may take place *per primam intentionem*, with almost immediate restoration of function; and, indeed, had others been able to confirm the experiments of GLUCK on the sciatic nerve of the fowl, or had he controlled his work by histologic examinations, we should have had to believe in the possibility of primary healing. But the weight of testimony is against this, and if we grant, as do nearly all modern writers, that union does not take place in this way, the views with regard to the regeneration of the nerve may be divided into three groups. According to that of NEUMANN, supported by EICHHORST and MAYER, the old myelin and axis break down completely in the peripheral end, and lie in the old sheath, regeneration being brought about by a differentiation of this broken-down material into a new axis and a new myelin, the new formation taking place discontinuously, but appearing first near the central end, and progressing toward the periphery. The second view is based on the theory that the axis-cylinder persists throughout the peripheral degeneration. WOLBERG believed that connection was established between the axis-cylinders of the central and peripheral ends by the formation in the intervening cicatricial tissue of entirely new fibers from the round or oval cells of the perineurium.

The ideas which have met with general acceptance, however, are those of WALLER and RANVIER, who assert that there is always a destruction of both axis and myelin in the peripheral portion, the new axis being formed by an outgrowth of the axis-cylinder of the central end. LEEGAARD, writing in 1880, maintained that the axis developed anew in the peripheral end, and became connected secondarily with that of the central end. Incidentally, it may be mentioned here that BENECKE and KÖLLIKER

have shown that the nuclei of the sheath play an important part in the development of the new myelin.

The whole subject has been recently taken up anew by HOWELL and HUBER,[1] in this country, who, after a careful review of the literature, describe their physiologic and histologic experiments, and the results obtained. The technique observed was essentially modern, and in many ways both original and ingenious. We are sorry that, on account of lack of space, we shall have to be satisfied with an epitome of their conclusions.

These writers find that, after division, a nerve never unites by first intention, but, as the histologic examination shows, undergoes complete degeneration in its peripheral end, segmentation of the myelin and axis occurring first at the intersegmental lines. After the first four days, there is entire loss of peripheral irritability, the gradual return of irritability and conductivity being delayed until about the twenty-first day. The sensory recover their function earlier, as a rule, than the motor nerves.

Arranging the histologic changes in the order of their sequence, there is, (1) following the segmentation of the myelin and axis, a proliferation and migration of the internodal nuclei; (2) a further disintegration and absorption of myelin and axis, associated with an increase in the amount of protoplasm about the nuclei. This soon results in (3) the formation of a continuous protoplasmic band, which lies in the old sheath; (4) a differentiation of the periphery of this band gives rise to a new sheath, when what is known as an "embryonic fiber" is complete, a structure which, while it contains neither myelin nor axis, is capable, after union with a similar protoplasmic outgrowth from the central end of the nerve, of carrying volitional impulses, though incapable of electrical stimulation. To the early development of such fibers we are probably to look for the explanation of those cases of rapid union after section which the surgeons report. (5) The new myelin next begins to appear in the peripheral end, first in isolated drops in the neighborborhood of the nuclei, and later, by a fusion of the drops; a continuous tube of myelin is thus formed. (6) Everything by this time being in readiness, the outgrowth of the new axis-cylinder from the central end rapidly follows, the superfluous nuclei slowly disappear, and the restitution is soon complete. The illustrations that accompany HOWELL and HUBER'S article make clear the successive alterations in the nerve better than any written description could do.

After such thorough work we can easily pardon the writers for indulging in a certain amount of speculation, especially as they have not allowed this to go further than the results of their researches would seem to warrant. But whether the nutrition of each internode is actually dependent upon the regular functioning of the internodal nucleus, and whether the latter is guided in its rule over metabolism by trophic impulses received from the nerve-centers through the axis-cylinder, are questions the answers to which, however probable the solution now proposed may seem, we must postpone until our knowledge concerning such obscure processes becomes clearer.

[1] Journal of Physiology, 1892, vol. xiii, p. 335.

DIABETIC COMA.

THE subject of diabetic coma has always attracted much attention from both clinicians and physiologic chemists. While, however, much has been done to increase our knowledge of the causation of this particular accident of the diabetic, it cannot be said that the ultimate cause of its appearance has as yet been entirely determined.

The view that acetone is the sole factor in its production has been proven false, this substance being found in the urine of patients other than diabetics, and in that of perfectly normal individuals, while SQUIRE has found it in the blood of patients with neither diabetes nor coma. There is more reason in the view that diacetic acid is the toxic substance, although this also has been found in those without diabetes. MINKOWSKI urges the view that β-oxybutyric acid is the toxic material, and has probably advanced one step nearer to the truth, as the substance named has been found in both the blood and urine of sufferers from diabetes. That one or the other, or both, of the last-named substances have at least much to do with the development of the coma is rendered likely by two circumstances—the similarity between diabetic coma and the symptoms of acid-intoxication experimentally produced in animals, and the results of intra-venous injection of an alkaline solution for the relief of the former. To be sure, the amount of benefit derived from this injection is much less than was at one time anticipated, but, so far as it goes, it proves that at least a lessening of the depth of the coma can in some cases be

caused by artificially increasing the alkalinity of the blood. In favor of the view that β-oxybutyric acid is at least a large factor in its production are the facts that diabetic coma is extremely likely to follow prolonged or excessive muscular exertion, and that β-oxybutyric acid is very closely related to the lactic acid of muscular tissue.

Lepine and Hugounenq in 1887 practised intra venous injection of a solution of sodium bicarbonate in a case suffering from diabetic coma, in whose urine and blood β oxybutyric acid was found in corresponding quantities prior to the injection. After the injection improvement occurred, and, although death ultimately took place, the β-oxybutyric acid was found to have disappeared from the urine.

It would seem, therefore, that acetone plays no important part in the production of diabetic coma; and this conclusion is borne out by the experimental injections of acetone made by Albertoni. The importance of diacetic acid and β-oxybutyric acid is clearly proven by the diminution (although in most cases but temporary) of the coma after the intravenous injection of alkaline solutions. That the acidity dependent upon one or both of these acids does not represent the total toxicity of the blood is shown by the fact that this improvement is, in the vast majority of reported cases, merely temporary. There must, therefore, be still another toxic element acting.

The foregoing statements are well confirmed by the report of a case by Roque, Devic, and Hugounenq, in the *Revue de Médecine* of December 10, 1892. Although extremely interesting from every point of view, the report may be said to be especially valuable for the chemical and experimental work performed with the blood. The patient was admitted to the Hôtel-Dieu in partial coma, and with a history of six days of premonitory symptoms. Sugar was found in the urine. The patient was bled to the extent of 300 grams, and 20 grams of sodium bicarbonate were administered before the occurrence of death—thirteen hours after admission. In this case, as in so many others reported, improvement followed the injection. Neither in the blood nor in the urine could β-oxybutyric acid be found. The alkalinity of the blood withdrawn prior to the injection showed, however, that its alkalinity was but 50 per cent. of the normal. By the addition of sodium bicarbonate to a portion of the blood its alkalinity was increased to the normal amount. Eight cubic centimeters of the unalkalinized blood were injected into a vein of a rabbit and produced death, preceded by convulsions; whereas twenty-three cubic centimeters of the alkalinized portion were injected in a rabbit of similar weight before death occurred. In the latter case, moreover, neither were the respirations so rapid nor the convulsions so severe as in the animal killed by the unchanged blood. In other words, the unalkalinized blood was about three times as toxic as was that to which the sodium bicarbonate had been added. In spite, however, of this diminution in toxicity, the blood was still capable of producing the death of the second animal also. In this case there was, therefore, present in the blood some acid poison, the nature of which was not determined, and the toxicity of which was not entirely neutralized by the addition of the alkali. Until the discovery of the character of this substance, not wholly dependent upon its acidity for its toxic property, our best means of combating this most grave symptom of diabetes consists in the intra-venous injection of alkaline solutions. That in the vast majority of cases disappointment follows its use, and that the improvement seen in some cases is merely temporary, should not debar us from persisting in the employment of such a measure, founded, as it certainly is, upon rational grounds and capable of ameliorating for a time this dangerous symptom against which we have no other more certain means.

EDITORIAL COMMENTS.

Audi Alteram Partem.—We were under the impression that in representing the sentiment of the medical profession as being unqualifiedly opposed to the unrestricted sale of patent medicines (we mean plain, every-day quack preparations, like "Hood's Sarsaparilla," "Jayne's Expectorant," "Winslow's Soothing Syrup," and the like), and to counter-prescribing by druggists ignorant of diagnosis, we voiced the unanimous opinion of physicians. It seems, however, that we were mistaken, and in a spirit of fair play we quote from an address entitled "The Physiology of a Menu," delivered before the Alumni Association of the Philadelphia College of Pharmacy by a prominent physician of Philadelphia (*The P. C. of P. Alumni Report*, January, 1893, p. 81), the following remarks:

"My student-hearers will learn, before long, about some of the questions that arise, such as, for instance, that druggists sell patent medicines, and that

they are criticised for doing some other things, as counter-prescribing, etc. I feel, in regard to these matters, that we, as physicians, had better let well enough alone. It is hardly necessary to enter into a deep discussion about the nostrum traffic, very largely for this reason: that the public demand nostrums and will have them, and it is better that the intelligent pharmacist should sell them than that the public should have to resort to the corner grocery, or a place of that kind. . . . I think that we have, as physicians, enough to do to take care of ourselves. It is our duty to cultivate such an elevated standard in our profession that we will not have to resort to nostrum-prescribing. It is necessary for you to do all you can to elevate and to raise the standard of the pharmaceutical profession; such an ideal standard as I have in the past had the pleasure of coming in contact with in my daily work. On our part we should attempt to do the same. I am sure that is the way with most men in the medical profession, and it will continue so."

The argument is forcible, and deserves extended application.

There is "a public demand"—*e. g.*—for houses of prostitution; therefore it would be much better for church-members to keep them than to allow the ignorant and the vicious to do so. Each man has enough to do to keep his own conduct clean without bothering about that of his neighbor.

Then, again, there is quite a large section of "the public" that "demands and will have" bogus medical diplomas. Evidently it would be much better to supply such parchments at respectable colleges than for "customers to have to resort" to vile institutions like that of Buchanan and his friends. How stupid it is, then, in the Medical Society of the State of Pennsylvania to try to have a law passed that will prevent the "intelligent professor" from meeting the demand. If we elevate the standard of our own colleges we need not bother about that of other States or of other sects.

What a fuss all these would-be reformers do make about trifles anyhow! It is much pleasanter and much more popular to leave ill enough alone. One makes fewer enemies, too.

The Conditions of Higher Medical Education.—We heartily commend the excellent words of our contemporary, the *Journal of the American Medical Association*, in reference to endowments, etc., quoted in another column. The wretched condition of medical education in our country has long enough been the subject of ridicule of other countries and of the best men among ourselves. It is a shame that the whole profession in the United States should set itself rigorously and vigorously to stop. State Boards of Examination are right, and should be established everywhere, but they are not sufficient. These can only properly raise their standards as the applicants for admission have been better prepared by the colleges.

About the following propositions it would appear there can be no possibility of discussion or doubt:

1. The minimum of study requisite for granting the degree of M.D. to students possessing no literary or scientific training, upon entering upon their medical studies, should either be four years, or three years of lengthened terms, with real and not sham entrance-examinations, and with a teaching and drilling in actual medical and clinical work that is adequate, and is not simply commercialism masquerading as medicine. Three years—such years as are usually passed—have become certainly and plainly insufficient.

2. No institution can adequately fit its students for their work without endowment or State aid. As a rule, the colleges possessing endowment will certainly prepare their students better than those without the necessary laboratories, the large corps of paid assistants, the enlarged teaching body, the drill of bedside instruction, etc.

3. The fixation of salaries of the teaching body is an absolute pre-requisite to elevation of standards, and a prevention of the graduation of the ill-fitted. It is also a pre-requisite for obtaining endowment, as neither individuals nor the community should endow or aid an institution whose profits and success are primarily for the benefit of individuals, and only secondarily and adventitiously of medical education and of the profession.

Model Dwellings for the Poor.—As a counterweight against the love of quackery by the gentlemen of "the cloth," one is occasionally delighted to find a member of the ministerial or priestly profession who shows an intelligent interest in sanitation and preventive medicine. Such interest is evident in a late lecture by Rabbi Joseph Krauskopf, of Philadelphia, on "Model Dwellings for the Poor." The practical, financial, and hygienic aspects of the question are kept well in view and dominate the entire treatment of the question. It is said that Philadelphia "has done more toward furnishing model dwellings to her poor than any other city."

"With a population considerably smaller than that of New York, we have more than three times the number of houses that the metropolis has, and they are for the most part the properties of their occupants, and while New York averages twenty persons to a dwelling, and Brooklyn ten, and Boston eight, our city averages but five persons to a house; and while the death-rate of New York is 25 per 1000 of its population, and that of Boston 24, and that of Brooklyn 22, we in Philadelphia are fortunate enough to be able to report but 19."

Not content with this showing it is proposed to

go much further, and to organize a "Model Dwelling Company," for erecting a building "that shall yield physical and moral health to a mass of depraved and suffering humanity." Aid is asked, and should be promptly given.

A Fifty-days' Fast.—The newspapers tell of the end of the exhibition-fast of Jacques, in New York. One wonders no longer at the stories that have been told by Chinese travellers, that a man could be hired to die for another for a good dinner. This phenomenal faster is said to have eaten nothing for fifty days, during which time he lost 32¼ pounds, having started in weighing 144½ pounds. During the last two days his sufferings are reported to have been very great, but whether these were real or simulated for theatrical effect, does not surely appear. The ever-present manufacturer of some "peptonized" material furnished Jacques at the end of his fast, some of his "food-product" (duly reported), and now furnishes the world with marked copies of the newspaper report, and with circulars of information in reference thereto. Jacques is also said to have gained during his fast one and one-fourth inches in height. Of course, he used pinches of a powder, for the secret of which the Russian Government offered $50,000. Famine, as is well known, is endemic in Russia.

The Ravages of Diphtheria.—According to the records of the Registration Department of the Philadelphia Bureau of Health, there were in 1892 5051 cases of diphtheria reported by physicians, of which 1484 were fatal. It is in the presence of such facts that the illogicality of popular feeling becomes startlingly manifest. One murder arouses more widespread interest than the thousands of deaths (many or most of which are preventable) silently taking place all over the world. The people who work themselves into a frenzy of enthusiasm over a selfish quack who makes millions of dollars by secrecy in treating a few old cases of often-merited "disease," have no thanks for the profession that unselfishly toils to prevent or cure the deaths of myriads of the innocent and the young.

The Profession and Public Scandal.—The New York *Herald* has at last stopped its daily columns of medical gossip as regards useless and hazardous surgical operations, in which so many members of the profession have aided it in its pernicious scandal-mongering. The result of it all is that the paper has filled its columns in a dull season, the enterprising doctor has gotten much free advertising, and the undiscriminating public has still more exaggeratedly erroneous and absurd suspicions and opinions upon matters about which it is incompetent to judge. The self-advertiser always plays into the hand of his half-brother the quack.

Expensive Economy.—An attempt is again being made to cripple the splendid work of the Surgeon-General's Office at Washington by a proposed omission or reduction in the usual appropriation for printing the catatogue of the library, and for the purchase of books. Every physician is either directly or indirectly interested in seeing that this is not done, and the members of the American medical profession should individually, or as societies, take action to prevent it. As reported to the House, the appropriation omits altogether the item for printing the catalogue (amounting only to $12,000), and reduces from $10,000 to $6000, the customary allowance for the purchase of books. Such economy, in the long run, is absurdly expensive.

Scheming and Frankness.—The medical politician who takes roundabout, secret, and snaky methods of "getting there," confesses two self-stultifying facts: First that his objects are not good and honest enough to be openly avowed; and second, that his strength and self-confidence are not sufficient to attempt the effectualization of his aims, except by chicane and subtlety. All the world recognizes what the politician thinks he is so expertly concealing from all the world, that is, that he is both unscrupulous and weak.

SELECTION.

ENDOWED COLLEGES AND HIGHER MEDICAL EDUCATION.

On the part of the colleges which propose to cater to students seeking short terms of instruction, the apology is made that however much they desire to keep step, forward and upward in the march, they cannot financially afford to meet the advance requirements.

Such institutions are in an unenviable dilemma, for they cannot stand still or paddle along in the old beaten paths. They are destined to either fall back into an innocuous desuetude, or are obliged by the new conditions to gird themselves anew for the exigencies that are before them.

The new conditions imply a provision of the necessary means for creating modern laboratories with accompanying apparatus and accessories of all kinds. Such needed adjuncts, including a trained corps of teachers, are to be obtained only through munificent endowments provided and bestowed by those who are bountifully blessed with this world's goods, or by State aid.

Endowments or State aid should only be given to medical schools having a practical relation with a university or academic college, as one of the post-graduate departments of such institutions. A nominal affiliation is not a sufficient condition. The one must be an integral part of the other. Such a relation naturally fosters and encourages a suitable preliminary course of study for those who propose entering the medical department, the curriculum of which should be, *de facto*, one of the post-graduate courses.

Teachers of the science of medicine in university medical departments should be paid regular salaries, the same as teachers in other departments, and open prizes offered for results of original research.

Teachers of the art of medicine need not necessarily be salaried men, as other emoluments naturally flow to the occupants of such chairs.

Large endowments have recently been made to the medical department of the University of Pennsylvania, the medical department of the University of California, the medical department of the Columbia University, the medical department of Johns Hopkins University, the medical department of the Western Reserve University (at Cleveland), to the medical department of the Chicago University, the medical department of the Northwestern University, the medical department of Dartmouth, and perhaps others; material, if not munificent State aid, is annually given by the Legislature of Michigan to the medical department of the State University; the same may be said of the Legislature of Minnesota, and, perhaps, of other States.

Such are the measures necessary for the promotion of the higher grades of medical instruction, and without such substantial foundations, medical colleges, the managers of which are conscious of their shortcomings, must make a change of front, squarely meet the issue that is before them, and show by their works an honest acceptance of the educational situation.

To the best of our knowledge neither State aid nor financial endowments have ever in any instance been bestowed upon commercial medical colleges, nor is it likely that we shall be called upon to make mention of such an institution. Moneyed men are usually too shrewd to give of their wealth for such individual aggrandizements.—*Journ. Amer. Med. Association.*

REVIEWS.

Diseases of the Eye, Ear, Throat, and Nose. By Frank E. Miller, M.D., James P. McEvoy, M.D., and John E. Weeks, M.D. Students' Quiz Series. Philadelphia: Lea Brothers & Co.

We doubt the advisability, even in a "quiz-compend," of attempting to compress an ophthalmologic epitome into one hundred and ten pages. The authors have succeeded as well as was possible. In view of the too prevalent custom of slip-shod refraction work, we are delighted to find the ophthalmometer of Javal and Schiötz spoken of as "an aid, in a limited sense, for the determination of refraction." It is therefore evident that it cannot be used as the sole instrument in cataract-extraction and medical science! "The trial-lenses must be depended on," etc. We can forgive anything after that, even though not a word is said about eye-strain, what it is and what it signifies, and not a word as to the symptoms of hyperopia and astigmatism—facts that make up about nine-tenths of an oculist's routine concern and work; and our pardon is especially full and free because of the wonderful New York words, "It is always well to employ a mydriatic."

Skiascopy is persistently spelled *skioscopy*.

As there are only sixty-four pages of this little work devoted to diseases of the throat and nose, it would be impossible to deal at length with the many subjects involved. Despite this fact, the subjects have been presented clearly and concisely. One commendable feature of the book is that of the various plates presented many are original, instead of being copied from text-books on the subject, which is usually the case.

The differential table of the signs and symptoms of the principal laryngeal diseases is an admirable one for both student and practitioner. One serious defect in the book is the failure to mention the forms of pharyngeal and laryngeal affections dependent upon lesions of internal organs, also those cases of pharyngitis that occur in patients of a highly nervous temperament—in other words, of reflex origin. We think these subjects too important to have been entirely omitted.

Fissure of the Anus and Fistula-in-Ano. By Lewis H. Adler, Jr., M.D. 12mo, pp. 78. Detroit Geo. S. Davis, 1892.

In this little *brochure* the author has endeavored to give a concise yet thorough account of the two affections—fissure of the anus and fistula-in-ano—in respect to their etiology, symptomatology, diagnosis, and treatment, and not to write upon rectal fistulæ in general.

To neglect, carelessness, want of cleanliness, a false sense of modesty, and the use of improper paper for toilet purposes are attributed the causation and aggravation of many of the rectal troubles encountered by the specialist.

The author insists that the diagnosis of these troubles, to be complete and satisfactory, must in every case be based upon an ocular and thorough digital examination.

The work throughout is modern and satisfactory, and it is to be hoped that in the attractive form in which it is issued it may enjoy a wide circulation and excite a deeper professional interest in rectal troubles than exists at this time.

Die Lehre von den Naseneiterungen, mit besonderer Rücksicht auf die Erkrankungen des Sieb- und Keilbeins und deren chirurgische Behandlung. Mit 5 Abbildungen. Von Dr. Ludwig Grünwald. Pp. 165. Munich. (On the Suppurative Processes in the Nasal Passages, with special reference to the Diseases of the Ethmoid and Sphenoid Bones and their Surgical Treatment.)

This pamphlet of Dr. Grünwald is a learned and elaborate monograph dealing with the diseases of the nose and associated chambers in which a purulent discharge is a conspicuous symptom. We cannot but believe that such a method of classification of nasal diseases is eminently artificial; nevertheless the author has brought together in a convenient form the acute and chronic suppurative processes in the regions named, and has treated the subject in a thorough and practical manner. Themes such as anosmia, parosmia, reflex headache, psychical phenomena, and atrophic changes are embraced in the main proposition. The surgical methods accepted agree with those in general use in this country. A full list of references to the literature of the subject completes this valuable essay.

CONTRIBUTIONS OF PHYSICIANS TO ENGLISH AND AMERICAN LITERATURE. By ROBERT C. KENNER, M.D. Pp. 93. Detroit: George S. Davis, 1892.

As far as it goes, this little volume is highly interesting, giving us brief notices and selections from the writings of Mark Akenside, John Arbuthnot, John Armstrong, Sir Richard Blackmore, Sir Thomas Brown, Walter Charleton, George Crabbe, James Currie, Erasmus Darwin, John W. Draper, Sir Samuel Garth, Oliver Goldsmith, Oliver Wendell Holmes, John Keats, Charles J. Lever, John Locke, D. M. Moir, T. G. Smollett, Henry Vaughan, and John Wolcott. When we lay it down we are tempted to ask for additional volumes, when we call to mind so many equally worthy, of whom our profession would be glad to know more as to their early struggles, their earlier writings, and what they did in our profession. We advise every physician to read this brochure, if for nothing more than the selections from our own Holmes, particularly "Rip van Winkle, M.D."

A HANDBOOK OF THE DISEASES OF THE EYE, AND THEIR TREATMENT. By HENRY R. SWANZY, A.M., M.B., F.R.C.S.I. Fourth edition. Philadelphia: P. Blakiston, Son & Co., 1892.

CONCERNING the fourth edition of this well-known and excellent work, the author says:

"The book has now again been revised throughout and brought up to date. In an appendix, Holmgren's method for testing the color-sense has been described in greater detail than before. Some new illustrations have been added. The great difficulty of an author in the preparation of a book like this consists in 'saying not all he might, but all he ought.' It is his duty to give a succinct and practical account of his subject in its most modern aspect, without weighting his pages with excessive detail and prolonged discussion. This has been my aim. For deeper and wider information, larger handbooks and original monographs must be consulted."

TRANSACTIONS OF THE TEXAS STATE MEDICAL ASSOCIATION, 1892. Pp. 310.

OF this class of medical literature this is a worthy volume. The work of the society being grouped in sections, the papers are considered and published in that order, enabling each to attend to the reading only of those which are in the line of his own work. Space does not permit of an extended notice of the papers, but all are well worth a careful perusal. We commend the manner of arranging the volume, giving at a glance, the officers, next place and time of meeting, etc. These points are often only found after a tedious hunt through the entire work, and cause unnecessary trouble to those who are interested in such data. We would, however, urge that in the next volume the Secretary publish the names and addresses of the officers of the auxiliary societies, or at least of their secretaries.

A MANUAL OF CLINICAL OPHTHALMOLOGY. By HOWARD F. HANSELL, M.D., and JAMES H. BELL, M.D. With 120 illustrations. Philadelphia: P. Blakiston, Son & Co., 1892.

THERE are very few things to blame, and many to praise, in this excellent little compendium. Within the self-imposed limits it may be recommended as one of the best of the smaller manuals upon ophthalmology. We cannot help wishing that a fuller treatment had been given to many subjects. Perhaps a somewhat frequent arbitrariness and apparent dogmatism would have been avoided if the authors had given themselves more room. To say or to imply, *e. g.*, that cocaine always "destroys the corneal epithelium and clouds its transparency," is decidedly an over-statement. Occasional grammatical sins also occur, as for instance: *The external recti-abduction, overcome in the average 8°.* Do the authors pronounce *fibre* or *fiber?* And if they pronounce the word as Americans do, why do they spell it as Frenchmen do? We imagine the authors may now wish they had omitted that relic of medievalism, the dedication!

NEWS ITEMS.

The International Congress of Charities, Correction, and Philanthropy, June 12–18, 1893.—One of the series of international congresses to be held in Chicago in 1893 is to be devoted to the subjects of Charities, Correction, and Philanthropy, and the Fourth Section of this is to consider all matters relating to the Hospital Care of the Sick, the Training of Nurses, Dispensary Work, and First Aid to the Injured. The Committee of Organization of the Congress has appointed Dr. John S. Billings, Surgeon U. S. Army, as Chairman of this Section, and Dr. Henry M. Hurd, Superintendent of the Johns Hopkins Hospital in Baltimore, as its Secretary, and has authorized and requested them to complete its organization, to extend invitations, and to prepare a program for its work. Miss Isabel A. Hampton, Superintendent of the Training School for Nurses of the Johns Hopkins Hospital, has been appointed Chairman of that part of the work of the Section which relates to the training of nurses.

This Section will hold five sectional meetings of about two hours each, commencing June 12, 1893, and will also have charge of one of the general sessions of the Congress, viz., that held on the morning of June 14th.

It is desired that this shall be a truly international gathering for conference on the subjects allotted to this Section, and all who are interested in Hospitals, in the Training of Nurses, in Dispensaries, or in First Aid to the Injured, are cordially invited to be present, to contribute papers and to take part in the discussions.

The papers and proceedings will probably be printed as a separate volume, and it is hoped that this will represent the best methods and the best work in each of these departments in all parts of the world.

The following are suggested as subjects for special consideration in papers to be prepared:

1. Hospital Organization—Governing Bodies—Relations of the Medical Staff and of Nurses' Training Schools.

2. Hospital Finances—Means of Support—Mode of Keeping Accounts—Cost.

3. Plan and Construction of Recently Built General Hospitals, embodying the Latest Improvements.

4. Relations of Hospitals to Increase of Knowledge, to Medical Education, and to the Medical Profession. Hospital Records, Statistics, and Reports.

5. Pay Patients in Hospitals.

6. Isolating Wards and Hospitals for Contagious Diseases.

7. Hospital Diets, Dietaries, Kitchens, etc.

8. Hospital Amphitheaters and Operating-rooms.

9. Hospital Laundries and Disinfecting Establishments.

10. Army and Navy Hospitals—Emergency Hospitals in Time of Epidemics—Temporary and Movable Hospitals.

11. Small and Special Hospitals, Cottage Hospitals, School Hospitals, Private Hospitals, Sanatoriums, etc. Convalescent Hospitals, and What to Do with Incurables.

12. History and Present Condition of Hospitals in the Large Cities.

13. Training Schools for Nurses.[1]

14. Dispensaries—Relations to the Public and to the Medical Profession. Dispensary Records.

15. First Aid to the Injured. Associations for the best means of popular instruction in First Aid to the Injured, and its Place in General Education.

Persons desiring to present papers, or to share in the discussions of this Section, are requested to communicate with the Secretary at once. The period of time allotted for the preparation of the program is necessarily brief and it is essential that all who are willing to assist in this work should act promptly.

The American Surgical Association will hold its next annual meeting at Buffalo, N. Y., May 30, 31, and June 1, 1893.

The following is a list of the subjects which have been selected for special consideration, with the names of the Fellows who have promised to prepare the opening papers upon the several subjects, and of those who are expected to open and take part in the discussions:

The President's Address.

"The Modern Treatment of Compound Fractures," by Nicholas Senn, M.D. Discussion by Drs. Roswell Park and F. S. Dennis.

"Hypertrophies and Degenerations of Cicatrices and Cicatricial Tissue," by J. Collins Warren, M.D. Discussion by Drs. C. H. Mastin, G. R. Fowler, and W. H. Carmalt.

"Surgery of the Gall-bladder," by M. H. Richardson, M.D. Discussion by Drs. J. Ewing Mears, A. Vander Veer, William H. Carmalt, and Theodore A McGraw.

"Surgery of the Rectum," by A. G. Gerster, M.D. Discussion by Drs. L. S. Pilcher, H. H. Mudd, and L. McLane Tiffany.

"Surgical Treatment of Cervical, Thoracic, and Abdominal Aneurism," by C. B. Nancrede, M.D.

"Surgery of the Prostate," by J. William White, M.D. Discussion by Drs. Hunter McGuire, Theodore F. Prewitt, R. F. Weir, and F. H. Gerrish.

"Treatment of Carbuncle," by F. Lange, M.D. Discussion by Drs. Robert Abbe, John B. Roberts, and J. S. Wight.

"Unreduced Dislocations of the Astragalus," by Stephen Smith, M.D., of New York.

The Section on Diseases of the Mind and Nervous System of the Pan-American Medical Congress announces that strong efforts are being made to insure the scientific and social success of the meetings. Papers are expected from distinguished neurologists and psychiatrists. A cordial invitation is extended to all physicians to attend the meetings and participate in the proceedings. Dr. A. B. Richardson, of Columbia, Ohio, is the English-speaking secretary, and Dr. R. M. G. Echeverria, the Spanish-speaking secretary.

[1] In accordance with the general program of the Section, nurses will take part in the general session and in two sectional meetings, and will hold in addition three separate meetings—June 13th, 14th, and 17th.

For these three separate meetings papers on subjects of special interest to Nurses will be prepared and discussed. The following are suggested as subjects to select from:

Training Schools in England and America.
Proper Organization of Training Schools.
Nursing in Infirmaries and Almshouses.
Nursing of the Insane. Obstetric Nursing.
Nursing of Infectious Diseases.
Nursing in Sanatoriums and Home Hospitals.
Private Nursing. Nursing by Religious Orders.
Work of Graduate Nurses.

All communications relating to this portion of the work of the Section should be addressed to Miss Isabel A. Hampton, Chairman, the Johns Hopkins Hospital, Baltimore, Md.

BOOKS AND PAMPHLETS RECEIVED.

Delivery through the Abdominal Walls *vs.* Craniotomy, in Otherwise Impossible Births. By George I. McKelway, M.D. Reprint, 1892.

An Obscure Case of Appendicitis Masked and Complicated by Ovarian Adhesions; Operation and Recovery. By George I. McKelway, M.D. Reprint, 1892.

The Use of Menthol through the Stomach-tube. By A. L. Benedict, A.M., M.D. Reprint, 1892.

The Laboratories of the College of Physicians and Surgeons of Chicago. Circular.

The Relative Safety of Ether and Chloroform. By W. Roger Williams, F.R.C.S. Eng. Reprint, 1892.

Discussion of Dr. Vaughan's Paper. By Bayard Holmes, B.S., M.D. Reprint, 1892.

A Case of Metastatic Abscess of the Brain; Operation; Death. By G. L. Walton, M.D. Reprint, 1892.

Du Traitement des Suppurations Rebelles du Sinus Maxillaire. Par le Docteur A. Cartaz. Reprint, 1892.

The Modern Antipyretics; their Action in Health and Disease. By Isaac Ott, M.D. Brochure. Second edition. Easton, Pa.: E. D. Vogel, 1892.

On Peripheral Neuritis. A Treatise. By James Ross, M.D., LL.D, and Judson S. Bury, M.D. London: Charles Griffin & Co., Limited, 1893.

Conclusions Regarding the Use of Drainage-tubes and Ligatures, and the Possibilities of Skin-disinfection based upon Bacteriological Investigations. By Hunter Robb, M.D. Reprint, 1892.

Transactions of the Medical Society of the State of North Carolina. Thirty-ninth Annual Session, held at Wilmington, N. C., May, 1892. Wilmington, N. C.: Jackson & Bell, 1892.

Observations on Cholera and Quarantine. A National Quarantine Implies National Seclusion. By C. W. Chancellor, M.D. Pamphlet. Baltimore: John Murphy & Co.

Transactions of the American Gynecological Society. Vol. XVII, for the year 1892. Philadelphia: Wm. J. Dornan, 1892.

Prospectus of the London Post-Graduate Course. Fourth Year. Spring Term, 1893.

Ueber die hypodermatischen Injektionen von Blutserum bei der Behandlung der Lungentuberkulose. Von Mariano Semmola. Reprint. Wien, 1891.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXII. SATURDAY, FEBRUARY 11, 1893. NO. 6.

ORIGINAL ARTICLES.

SHOULD WE TREAT FEVER?[1]

BY S. T. ARMSTRONG, M.D., PH.D.,
VISITING PHYSICIAN TO THE HARLEM HOSPITAL, NEW YORK.

IT is almost unnecessary to offer any excuse for presenting for consideration so familiar a topic as is fever, because, as frequently as it is encountered in the routine of our daily work, it is nevertheless surrounded by some of the most abstruse problems in medicine, when we consider its etiology and treatment. More than six hundred different names are given under the caption FEVER in Foster's *Encyclopedic Medical Dictionary;* and although many of these may be appellations for the same disease, still their number affords an idea of the multifarious phases in which fever is encountered.

Pathologists and clinicians have not yet agreed regarding the cause of the manifestation of fever in the animal organism. The late Austin Flint, in an address delivered before the Ninth International Medical Congress (THE MEDICAL NEWS, September 10, 1887), said that "an essential fever is an excessive production of heat in the body, induced by a special morbific agent or agents, and due to excessive oxidation, with destruction of the tissues of the body, and either a suppression or a considerable diminution in the production of water." He intentionally ignored the causative influence of the nervous system.

W. H. Welch showed in his Cartwright Lectures (THE MEDICAL NEWS, April 7, *et seq.*, 1888) that the most frequent cause of fever was some substance that exerted a pyrogenic effect when introduced into the circulation, so that it could act in some way upon the nervous system. Welch considered that if it was assured that these substances incited directly in the blood and tissues chemical changes that led to an increased production of heat, it was even then necessary to have recourse to some action that was exercised upon the nervous system, in order to satisfactorily explain the phenomena of fever.

Samuel (*Real Encyclopädie der gesammten Heilkunde*, art. "Fieber") defines fever as an elevation of temperature that is evoked in consequence of a lesion of the heat-centers. Donald Macalister, in his work on the nature of fever, expressed the opinion that physiologic and pathologic experiments had shown that pyrexia depended on impairment of the inhibitory force by which the heat-producing process is kept within normal physiologic grounds—that is, impaired thermotaxis; upon an increased activity of the process by which the heat is naturally formed, that is, exalted thermogenesis; and upon a more or less complete failure of the process by which heat is discharged—that is, a failure of thermolysis. If we accept this latter explanation, and each year's discoveries add force to the reasons now existing for such acceptance, the infection of the blood by any organic product is simply the means of reaching the nervous centers, thereby producing the phenomena of fever. It must be stated that this theory is not universally accepted, Professor Arnaldo Cantani believing (*Transactions of the Tenth International Medical Congress*, vol. i, p. 152) that fever is an acute alteration of organic metabolism, with increase of tissue-combustion, thus agreeing with Flint, though overlooking Welch's warning that even with this theory it was necessary, in the last analysis, to have recourse to the action of the heat-centers.

Most clinicians accept fever as the principal index of the course of an infective process in the animal organism; and the question must be decided, in each case of fever, whether the infection is autogenetic or heterogenetic. We know that certain poisons, such as strychnine, veratrine, nicotine, and picrotoxin, will produce fever when given in certain doses. In certain digestive disturbances the peptones formed during digestion may gain access to the general circulation, and produce an autogenetic infection-fever, analogous to the ferment-fever that Hildebrandt has produced in dogs by the subcutaneous injection of pepsin. Vaughan and Novy have called attention (*Ptomaïnes ana Leukomaïnes*, Philadelphia, 1891) to this intra-organic formation of poisons, and they emphasize the importance of the subject by saying that "a man may drink only chemically pure water, eat only that food which is free from all adulterations, and breathe nothing but the purest air, free from all organic matter, both living and dead, and yet that man's excretions would contain poisons." They consider that it is unimportant whether the proteid molecule is broken up by organized ferments (bacteria), by unorganized fer-

[1] Read before the New York State Medical Association, November 17, 1892.

ments (the digestive juices), or by those unknown agencies that induce metabolic changes in the tissues, for in all cases poisons, differing in quality and quantity according to the proteid that is acted upon, will be formed. These poisons produce the autogenous fevers known as fatigue, exhaustion, thermic, non-eliminative, nervous, and hysterical.

Whatever cause may produce the fever, there is always an increased temperature that physiologists have shown is due not merely to a diminution of the loss of heat, but chiefly to an increased production of heat, as calorimetric observations have proved. Increased heat-production alone would be insufficient to raise the temperature of the body if there was a compensating increase of loss of heat; but this compensation is wanting in fever, and it has been designated the most characteristic feature of the febrile condition. Besides the ataxia of the thermal centers there are increased metabolism, as is evidenced by the augmented excretion of carbon dioxid, of urea, and the other urinary products; greater frequency in the number of the heart-beats, and in the respiration; diminution of the digestive activity and intestinal movements; and general disturbances of the organic functions.

From this *résumé* of the febrile phenomena it may be deduced that pyrexia, as seen by the physician, is the expression of certain pathologic processes that interfere with the physical and mental welfare of the person affected, and that consequently demand treatment.

When those interested in the history of medicine read the works that served to guide and instruct our predecessors of the first half of this century, and learn therefrom the then prevalent practice of starving the fever-patient, they will entertain a high regard for Dr. Graves, whose teaching assisted in securing the abandonment of this practice, and who said the only epitaph he desired was: "He fed fevers." And while there may be unanimity of opinion regarding this point, the physician is confronted in this *fin de siècle* by another problem that cannot but be an absorbing one, for there are those that urge, though they may not seek epitaphic renown, that there should be no treatment for fever *per se*. Are we to throw, so to speak, our antipyretics to the dogs? Is fever a beneficial organic reaction to the metabolic and hemic changes produced by the causative agent of the disease? Osler, in his recent work on the *Practice of Medicine*, says: "Fever alone is not hurtful, but it is difficult to differentiate the effects of fever and of the poisons circulating in the blood. It is not impossible, as some suppose, that the fever may be directly beneficial; still, high and prolonged pyrexia is undoubtedly dangerous and should be combated." And Lyman, in his more recent work on the *Practice of Medicine*, says: "The elevation of temperature that marks the course of fever is not an unmixed evil, yet it is customary to attempt its reduction." Each of these authors seems to have accepted the fever-process as explicable by the seemingly fantastic German theory of the day that fever is in the nature of a reparative process. In just what way it is reparative we are not informed; and it is as impossible to say with our present knowledge, in exactly what way fever accomplishes any useful purpose, as it was when Welch published his classic study on the subject of fever.

The conclusion formulated by Austin Flint in the address heretofore referred to, that "the abstraction of heat by external cold, and the reduction of temperature by antipyretics administered internally, without affecting the special cause of the fever, improve the symptoms which are secondary to the pyrexia," expresses the practice and belief of most physicians.

Reference has been made to the influence of certain alkaloidal poisons in increasing the temperature, presumably in consequence of their effect upon the heat-centers. But recently, Dr. E. Maurel has published (*Bulletin de Thérapeutique*, 1892, cxxii, p. 259) a series of experimental researches on the action of these alkaloids on leukocytes, and he finds that the toxic action of the alkaloids on the animal economy is in the ratio of their destructive action to the leukocytes. For example, five centigrams of strychnine will immediately kill all the leukocytes in one hundred grams of human blood, while two centigrams of that drug will effect the same result in the same quantity of blood in several hours. Five centigrams of atropine would also instantly kill the leukocytes in one hundred grams of human blood; although in the blood of the hare, an animal that eats belladonna with impunity, the alkaloid was almost without effect upon the leukocytes in the strength of two grams of atropine to one hundred grams of blood. Pilocarpine kills the leukocytes in human blood in a dose of ten centigrams to one hundred grams of blood. These experiments forcibly demonstrate the important relation existing between the leukocytes and the functions of the organism, and give force to Metschnikoff's theory of the relation between phagocytosis and immunity from disease. If these drugs that may produce fever are toxic to the leukocyte, should our treatment of fever have in view the preservation of the leukocyte under the best conditions, because in fever we have poisoning by animal rather than vegetable alkaloids?

The experiments that were made with the product of the tubercle-bacillus are not so old that we have forgotten the fever that soon followed the hypodermatic injection of a small quantity of tuberculin.

The injection of the products of the cholera-spirillum is also followed by fever, a result that is subsequent to the hypodermatic injection of the products of several of the infectious microörganisms. Such a fever, though usually enduring only a few hours, may be sustained by repeated injections of the toxin-product employed. It is therefore apparent that the microörganism causes fever by the production of its leukomaïn or toxin, rather than by the presence of the organism itself in the body.

It is possible to adduce further evidence of the influence of the increased toxicity of the blood in producing disturbances of the thermal centers, just as an analogous autogenetic increase of the toxicity of the blood-serum causes disturbances of the convulsive centers. The recently published experiments of Bouchard have shown that during puerperal convulsions the urine is diminished in quantity, and that it is less toxic than usual, so that effete products that should be excreted are retained in the animal organism. Dr. Chambrelent has proved (*Lancet*, September 24, 1892) the latter statement to be a fact, by supplementing Bouchard's experiments with the urine by those he made with blood-serum that he also obtained from women suffering with puerperal eclampsia. Chambrelent's results showed that the poisonous properties of the serum were constantly related to the gravity of the case, so that increased autogenetic infection augmented the severity of the convulsions.

The high temperature of fever cannot exercise a fatal influence on the specific microörganisms with which we are acquainted, because they develop most favorably at temperatures of from 35° to 40° centigrade, so that the usual febrile temperatures are best suited to their growth. This would seem as if fever was more useful to the microörganism than to the animal organism. Robert Koch regards temperature as the most important factor in the process of attenuation of the microörganisms, the temperature effect being aided perhaps by certain products of tissue-change in the bacilli. That these latter products are the more important in producing this attenuation is shown by the existence of the cholera-spirillum, the typhoid-bacillus, and other specific microörganisms in the tissues of persons affected by the respective infectious diseases after all febrile phenomena have ceased.

The brothers Klemperer have shown that in animals inoculated with the pneumonia-coccus, temperatures varying from 40° to 41° centigrade were reduced to normal in twenty-four hours after the injection of serum from another animal that possessed immunity to pneumonia. They believed that the pneumonia-coccus generated in the animal organism a product that they called pneumotoxin, that produced elevation of temperature; the pneumotoxin in its conflict with the leukocytes generated an anti-pneumotoxin that neutralized both the pneumotoxin and the pneumonia-coccus. They injected the blood-serum of persons convalescent from pneumonia into six pneumonic patients, and in from six to twelve hours subsequently there was a decided fall of temperature that remained normal in two of these patients.

Metschnikoff, Golgi (*Phagocytisme dans le Paludisme*), Gamaleia (*Annal. de l'Institut. Pasteur*, 1888, p. 229), and Laveran (*Traité des Fièvres palustres*) agree that febrile heat acts like artificial heat in increasing the activity of the leukocytes so that the parasitic elements become more easily their prey than in an individual in whom the temperature is normal. Metschnikoff (*Annal. de l'Institut. Pasteur*, 1887, p. 329) states that in relapsing fever the febrile access lasts during the free life of the spirilla in the blood, and ceases when these parasites become the prey of the leukocytes.

Here again we see the disposition to make the fever a reparative process; and yet clinical and experimental facts do not wholly warrant the deduction. In the experiments of the Klemperers already cited, the fever was insufficient to increase the leukocytic activity to a degree that disposed of the pneumonia-coccus and prevented the formation of additional pneumotoxin. It had been proved that the latter by itself caused fever; therefore it is a justifiable inference that the persistence of fever for from six to twelve hours after the injection of the serum from the pneumonic convalescents was due to the pneumotoxin present in the blood at the time the injection was made; and the subsequent decline in temperature was caused by the destruction of the pneumonia-cocci by the serum and consequent cessation in the formation of pneumotoxin.

In paludal poisoning the fever persists or recurs as long as the specific hematozoa are present in the blood. Quinine has no special influence in inciting leukocytic activity, at least as a principle applicable in all diseases. Yet the administration of quinine, by destroying the specific organism of paludal disease, ends the fever that never plays the rôle of a reparative process therein.

Opposed to this deduction are the experiments of Alexander (*Bresl. ärzt. Zeitschr.*, 1884, Nov. 11), that showed that the number of spirilli in relapsing fever increased when the temperature of the affected person was lowered by antipyrin. Wagner (*Ann. de l'Institut. Pasteur*, 1890, p. 571) showed, as Pasteur had shown before him, that fowls exposed to cold became capable of acquiring charbon; he considered that this occurred in them because the leukocytes lost a portion of their activity, and he was able to produce the same effect by lowering the temperature of the fowls by antipyrin.

Professor A. Rovighi, in the report (*Le Mercredi médical*, Aug. 3, 1892) of the results of his experiments made to determine the influence of artificial elevation and depression of temperature upon the course of infective processes, stated that he inoculated rabbits with human saliva, which was poisonous for these animals; he placed some of them, together with uninoculated rabbits, in a thermostat in which the temperature oscillated between 36° and 40° C. Other inoculated rabbits were kept in ordinary cages, while still others were placed in cold chambers and in cold baths, in which their temperature did not exceed 40° C. Death occurred earlier in the latter animals than in those in the thermostat; in fact, these latter died more slowly than those in the ordinary cages. But if the temperature of the rabbits in the thermostat exceeded 43°, death occurred quickly. Elevation of temperature occurred much more rapidly in the infected than in the uninfected animals in the thermostat. The loss of weight was much greater in the animals exposed to a lower than in those exposed to a higher temperature. At the point of inoculation in the latter there was an abundant fibrinous exudate containing a large number of leukocytes, while in the refrigerated animals the exudate was sero-purulent and less rich in leukocytes. The blood of the animals in the thermostat was much more toxic than that of those refrigerated, evidencing an increased formation of toxins in the former; though cultivations succeeded better if made from the blood of the refrigerated animals, because it more frequently contained the living microörganism.

Rovighi also inoculated rabbits with mouse septicemia; and those to which he subsequently gave acetanilid rapidly succumbed to a considerable decrease of temperature, while those infected in the same way that were placed in a thermostat presented no other morbid phenomena than an induration at the point of inoculation. He also found that rabbits and guinea-pigs inoculated with charbon survived longer if kept at a high than if kept at a low temperature, the charbon-bacillus appearing in the blood of the former later than in that of the latter.

Walter has published (*Archiv für Hygiene*, 1891, Bd. xii. p. 329) the results of experiments upon the artificial elevation of the temperature of the body on the course of infection with the pneumonia-coccus, in which he found that high temperature prevented the passage of the organism into the blood.

While it appears to follow from these experiments that an elevation of temperature to a certain degree exercises a favorable influence upon the infected animal, and that a lowering of temperature increases the intensity of the infective processes, it must be remembered that these are extraneous influences, while fever is an intrinsic influence. The observations of Röhrig and Kuntz, Colosanti and Kukler, Theodor and others have shown that gaseous exchange, and particularly tissue-oxidation in febrile animals, are much more intense in those exposed to cold than in those kept in thermostats. Yet these results are at variance with clinical facts, for it cannot be denied that the best results in treating typhoid fever have been obtained by the use of cold baths that keep the temperature below 40° C.; and if these increase the intensity of the febrile process and of tissue-oxidation, we are led to believe that the patients of those that use them recover in spite of, rather than on account of, the treatment that is only useful in increasing the elimination of toxic products.

The researches of Penro have shown that karyokinesis and the regeneration of tissue are affected much more rapidly at a temperature of from 34° to 38° than at a temperature of from 7° to 12° C.; but it has not been shown that karyokinesis and tissue-regeneration are affected at a temperature of from 38° to 40° C., as well as at the lower temperatures that antipyretic treatment endeavors to secure, and never does that treatment seek to reduce the temperature below 37.2° C., at which, experiment has shown, these processes are most effectively performed.

If the statements that "fever alone is not hurtful," or that "fever is not an unmixed evil," are based on the production of artificial fever in animals by inoculation, it is necessary to remember that in the latter such a fever only reaches a temperature of from 1° to 4° F. above the normal temperature of the animal; and if based on the fever produced by prolonged confinement in thermostats kept at high temperatures, the animal's temperature in such instances was only 4° to 5° above normal. Such rises of temperature are not regarded with any alarm when they occur in man; but while we may not look upon them as intrinsically hurtful or evil, they certainly cannot be regarded as beneficial or good. A fair analogy to the treatment of moderate rises of temperature is that of the treatment of pain. Each condition is indicative of irritation of certain portions of the nervous system; and though it has been maintained that pain is beneficial, it is the popular plan to relieve it at once whenever it appears, subsequently attending to the disturbing factor of which the pain was the index. So, I believe, we should deal with fever; relieve it by suitable antipyretics whenever it appears, and then give those remedies that will eliminate the exciting cause.

In this review of the question whether it is desirable to relieve pyrexia by the administration of antipyretics, the following points have been held in view:

1. That fever is the expression of some disturbance of the thermal centers.

2. That while this disturbance may be traumatic, it is usually the result of the existence in the organism of certain autogenetic or heterogenetic (infectious) products that have the same affinity for the thermal centers that certain vegetable alkaloids have for certain cerebral centers.

3. That fever does not exercise any beneficial effect in limiting an infectious process; this is a fact that has been known clinically for years by the occurrence of cases of infectious disease that pursued their usual course without any rise of temperature.

4. That it is the general experience of clinicians that the relief of fever exercises a beneficial influence on the general condition of the patient, though the apyrexia does not indicate that the cause of the pyrexia has been removed.

5. That in many febrile conditions the causative principle has produced a thermotaxic paresis that is at once relieved by some suitable antipyretic.

6. That in continuing the employment of antipyretics we are not losing sight of the possibility of obtaining, either synthetically or derivatively, compounds that will, when administered in the specific diseases, have the same inhibiting influence on the further development of the microörganisms of those diseases that certain alexins, toxalbumins, or toxins have. The action of such compounds should be as specific in each infectious disease as is the action of quinine in paludal fevers.

ECLAMPSIA GRAVIDARUM ET PARTURIENTIUM.

BY J. LINDSAY PORTEOUS, M.D., F.R.C.S. ED.,
OF YONKERS, N. Y.

THE word "Eclampsia" is said by some authorities to be derived from ἐκ and λάμπω, I shine—because, in some forms of convulsions, flashes of light appear before the eyes, but the derivation that seems to us the best to describe the disease is ἐκ and λαμβάνω, I seize hold of, as in every form of this malady the patient clutches at something, real or imaginary.

Anyone who has had experience in obstetrics must have noticed that there are several varieties of this dreaded disease. Some, to those conversant with such cases, give little alarm; but unless the physician can promptly diagnosticate one form from another, much mental worry is occasioned both to himself and the friends of his patients. The object of this paper is to give some hints, the outcome of years of practice, to those of less experience.

There are at least five varieties, viz.: (1) hysteric, (2) epileptic, (3) uremic, (4) apoplectic, (5) microbic.

1. The first form (HYSTERIC) need give little cause for alarm. It is, as a rule, confined to the period of gestation, but may continue throughout the period, at intervals, until labor sets in. When, however, the throes of labor begin and there is something of a realistic nature to occupy the mind, it vanishes. As the symptoms of hysteria are so well known to every physician, we will only take a cursory glance at them. Beginning with a tightness about the throat and the "globus hystericus," the attack is attended with sobbing and frequent attempts to swallow. Then the patient may become still or roll about. The hands clutch something or are carried to the breast or some other part of the body. The face is sometimes pale, though not always. There is no froth issuing from the mouth, no tongue-biting, no falling in a dangerous place. A very prominent feature is the quivering of the eyelids. The fit terminates, after a longer or shorter period, with a scream and the shedding of tears, and a quantity of limpid urine is often involuntarily discharged. As a rule, this form of eclampsia causes no interference with gestation, although premature labor is said to have been caused by it. The treatment, being so well known, need not be gone into at the present time.

2. EPILEPTIC.—For the sake of a more correct and sytematic diagnosis, we will adopt the Brown-Séquard method of dividing the symptoms into three distinct heads: (A) the premonitory, (B) the paroxysmal, (C) the inter-paroxysmal.

A. The *premonitory* are in many cases well marked; although the classic or Galenic aura is not often a prominent premonitory feature of this form, there are many others almost always present. To economize space, we will summarize the more important symptoms: A vague, indescribable sensation is *sometimes* complained of. Irascibility of temper; a vascular contraction in feet and hands, producing a falling in temperature; a spasmodic state of some muscle, or an optical illusion or hallucination, are almost always present, singly or collectively. Numerous other symptoms which have been noticed by different observers we need not refer to.

B. The *paroxysmal.* In this stage the symptoms vary according to whether the attack is one of epilepsia mitior (*petit mal*) or epilepsia gravior (*haut mal*). In the former there may only be the unconscious state, with a fixed condition of the muscles of the eye or contraction of one or more muscles of the face, or a movement of the lips, tongue, and throat as in the act of swallowing; or, according to D. Russell Reynolds, the patient may be only unconscious, *i. e.*, have simple loss of perception and volition. In such case the duration of unconsciousness is so short (from one to four seconds) that the casual and inexperienced observer does not notice it. Epi-

lepsia gravior, on the other hand, presents a very complex state of affairs. There is contraction of the bloodvessels of the brain and face, with consequent face-pallor, loss of consciousness, congestion at the base of the brain and of the spinal cord, tonic contraction of the laryngeal, cervical, and some of the respiratory muscles (laryngismus and trachelismus), the peculiar cry, and falling backward or forward. There is also tonic contraction of the muscles of the limbs. The difficult breathing prevents the entrance of the blood into the chest and its issue from the cranio-spinal cavity. Asphyxia, contraction of bowels, bladder and womb, are present, with coma, fatigue, headache, and sleep. The urine has often been observed to contain albumin, although there was no evidence of renal disease.

c. *Inter-paroxysmal.* The general health of epileptics is usually poor. They are excitable. Their memory is bad and they are subject to fits of depression. Their digestion and circulation are often affected. These do not take a form which is peculiar to this disease; neither does their morbid condition of mind have any peculiarity, nor are they necessary concomitants of epilepsy. The frequency of attacks varies greatly—some may have them daily for years, others may have a period of many years between the attacks. The more violent the convulsion the less seldom the attack.

Prognosis. Inherited epilepsy is seldom cured. Brown-Séquard says positively that some cases may be cured. A chance of cure is greater when some curable or amendable organic alteration exists as the cause, than if such were not the case.

If the cause can be traced to syphilitic brain-disease, the chances of cure are most favorable. If tumor of the brain be the cause, modern cerebral sugery may often be employed with certain success. There seems to be no necessary complication, but chronic nephritis, disease of the womb or other viscus may favor these convulsions. In the pregnant woman, death of the fetus or premature expulsion is to be dreaded more than the immediate danger to the mother. We do not consider that the mother runs more risk from this form of convulsion *because* she is pregnant.

Treatment. Our chief object in treating this disease in the pregnant or parturient woman should be to curtail the duration, frequency, and severity of the attack, in order that she should go safely through her full term of pregnancy and have sufficient strength for the final efforts of parturition. The means we adopt to accomplish this end may, for the sake of covenience, be divided into three heads: (1) What to do at the outset of a paroxysm; (2) What to do during a paroxysm; (3) What to do between the paroxysms.

In case of the existence of a real aura, several means for the prevention of the development may be employed. Galen advised a treatment which is often successful, but the reason he gave has by Brown-Séquard been proved to be entirely wrong. The Galenic reason was that, by tying a ligature round a limb, it barred something from going to the brain. On the other hand, Brown-Séquard has proved that the preventive effect was caused "by sending an irritation toward or rather to the nervous centers." We have tried this with much success. The best way is not to apply the ligature and leave it, but to apply and to remove it repeatedly. It is not necessary, according to the same authority, to apply it to the limb when the aura is felt. If a premonitory symptom is disturbance of respiration, the administration of chloroform may give instant and sometimes permanent relief. Immersion of the hands in warm water, giving stimulants, applying ice to the nape of the neck, may each or all be applied successfully. If we can find a part of the body which, by irritation, gives rise to an attack, we should apply counter-irritants to that part. If this part be the central organ of the nervous system, the spinal marrow, which is acted upon by an excited condition of those nerves passing from the uterine organ to the spinal center, depending upon the puerperal state or upon actual labor, counter-irritants will be of little service. While these stimuli continue to influence the spinal marrow, epileptic convulsions may be caused in either of two ways: those acting permanently on the spinal marrow, or centric causes, and those affecting the extremities of its incidental nerves, which are causes of excentric or peripheral origin. According to Tyler Smith, those acting immediately on the central organ are: (1) Pressure on the medulla oblongata by congestion-coagula, nervous effusion within the cranium; (2) Loss of blood; (3) Morbid elements in the blood, the influence of emotion.

Of causes acting on the extremities of the excitor nerves we have: (1) Irritation of the incident spinal nerves of the uterus and uterine passages; (2) Irritation of the excitor nerves within the cranium; (3) Irritation of the incident spinal nerves of the rectum; (4) Irritation of the ovarian nerves; (5) Irritation of the gastric and intestinal branches of the pneumogastric nerves; (6) Irritation of the incidental spinal nerves of the bladder; (7) As probable causes may be enumerated: irritation of the cutaneous nerves of the mammæ and hepatic and renal branches of the pneumogastric. Of course, the centric and excentric causes may act together. Over many of the conditions named we have no control. At all times, however, we should attend to the condition of the alimentary canal and kidneys.

Treatment during the paroxysm. Lay the patient in the supine position; loosen the clothes. Use only

sufficient force to prevent the patient from injuring herself. Careful administration of chloroform is often useful when a status convulsivus occurs. If, however, the attacks are so frequent that they threaten death by exhaustion, or a miscarriage is imminent, or the period of gestation is within two months or even longer of completion, the most rational and best treatment in our experience is to hasten on labor and deliver as quickly as possible. The safest mode of performing this is by digital dilatation, which may be accomplished in from one hour and a quarter to two hours. This is simple enough, with an assistant, to dilate by turns.

In the inter-paroxysmal stage, if the convulsions are not of a serious nature, we must search for a cause and treat it.

There may be albumin in the urine, but not necessarily so, as we maintain that with this form of eclampsia the kidneys have little to do. About 9 per cent. of pregnant women have albumin in the urine some time during gestation, but convulsions do not occur in 9 per cent. of pregnant women.

3. UREMIC CONVULSIONS.—Whatever may be the primary cause of this form of convulsion, whether mechanical or chemical, most authorities agree that it is a strike on the part of the eliminative organs. The symptoms may in many points resemble those of epilepsy.

In some cases there may be no loss of consciousness, but in all cases there is an abundance of an albuminous body in the urine, and a great diminution in quantity, sometimes total suppression. The attacks may resemble tetanus. There may only be one, coming on without warning or preceded by headache, giddiness, and drowsiness, or numerous convulsions may take place in rapid succession. Death has occurred during the attack, but not frequently during the puerperal state (if there is no true renal disease), because their origin in this state is a combination of circumstances which does not long persist, as either nature or art comes to the rescue. As there is no structural change in the kidney, there is no serum-albumin.

Treatment. Reëstablish as quickly as possible the action of the eliminative organs. Apply poultices over the loins; use the hot pack; give hydragogue cathartics and digitalis; perform venesection up to 8 or 10 ounces; give diaphoretics, as pilocarpine, etc. If all this treatment is of no avail, we must consider the advisability of bringing on labor as in the previous case.

4. APOPLECTIC CONVULSIONS.—Although this form, strictly speaking, should not be put under the head of eclampsia, it does sometimes happen that a patient is so seized during gestation or parturition, and we ought to be prepared to diagnosticate the condition when present. It may be defined as loss of consciousness, of sensation, and of voluntary motion, coming on more or less suddenly, and due to a morbid state of the brain (Gowers).

Symptoms. The onset is often sudden. The face is generally, but not always, flushed. The heart and arteries beat more forcibly than normal, but less frequently. Respiration is labored and stertorous. In profound coma, pupils are dilated, and sluggish in their reaction to light. The sphincters become relaxed. There is often paralysis of one side. The temperature is at first always lowered, but rises in from twelve to twenty-four hours.

The condition may be mistaken for syncope due to cardiac inaction, but we trust that the mistake is not frequently made. In cardiac syncope the heart's action fails, the pulse is weak and almost imperceptible, the face is pale, respiration is sighing and irregular, and the sphincters are rarely relaxed. Albumin is often present in the urine in cases of cerebral hemorrhage. If the patient is young, and there is general edema, the case is more likely one of uremia than apoplexy. The coma is more profound in cerebral mischief than in uremia, although the patient may be roused in many cases. Convulsions may come on at the onset, but they are generally unilateral. In uremic poisoning there are *general convulsions* at the onset. Coma in apoplexy comes on suddenly; in uremia, slowly.

Treatment. Remove all constrictions around the neck. Apply sinapisms to the back of the neck and to the extremities. Carefully administer stimulants when embolism or thrombosis is suspected. Strong purgatives, such as croton oil, lessen the serum in the blood, and remove it from the brain. Apply cold to the head. Little else can be done; much interference may cause baneful results.

5. MICROBIC CONVULSIONS.—We are not aware that any notice of this form of convulsion has been given in text-books, and we are aware that not until the 25th of March of this year, had a microbe been discovered. On that day two French physicians announced that they had found the microbe of puerperal eclampsia. The symptoms can be best given by describing a recent typical case observed by the writer.

On a Tuesday in the month of April last, we called on a lady who expected to be confined the following month. She looked the picture of health; was cheerful and hopeful; had *no drowsiness* or feeling of fatigue. She was walking about her house, and, in fact, felt perfectly well. She had no anasarca, and both kidney, and bowels were performing their functions thoroughly. The urine contained no albumin; it had specific gravity of 1022, and was slightly acid. At 1 A.M., Wednesday, we were notified that the membranes had ruptured without pain. At 7 A.M. we visited her and found that she had slight labor-pains, which continued at long intervals till noon, when suddenly, without warning, she had a

convulsion which lasted about ten minutes. The twitching was only slight; there was no quivering of the eyelids, no frothing at the mouth, no pressing of the thumb on the palm. The face was at first pale, then gradually became of a purplish hue. The pupils were normal in size, but did not respond to light. The pulse rose to 98. The woman recovered consciousness almost at once, and vomited. There was a slight feeling of exhaustion, but nothing else to indicate her late condition. At 1 P.M. there was another very slight convulsion. Dreading more, we determined to hurry on labor and deliver. With the aid of D. E. Hermance, we anesthetized her deeply, and by persistent digital dilatation delivered her with forceps in one hour and twenty minutes of a dead child. When the effects of the anesthetic had passed away she felt comparatively comfortable. This condition remained till 7.30 P.M., when she had in rapid succession three slight convulsions. During the night she voided quite a quantity of urine, and slept well. All Thursday her condition seemed quite favorable. At night she had, on the suggestion of a physician, a small hypodermatic of morphine. At 7 A.M., Friday, we were told that she could not be awakened. The nurse had noticed during the night her twitching frequently. We immediately tried to restore consciousness, which, to the extent of an attempt to speak, we did. Steaming her, hypodermatics of pilocarpine, enemata, were tried without effect. A pint of urine was removed by catheter and found perfectly free from albumin. After numerous slight convulsions she died at about 4 P. M.

We noticed no symptoms which might be said to be peculiar to this form, but there was the absence of the prominent symptoms in the previous four forms of eclampsia. There were no premonitory symptoms whatever which might give us a clew to the cause. The treatment pursued, we maintain, was quite justifiable. Until we know of a positive destroyer of this puerperal microbe, we can only try to drive it out of the system by exciting all the eliminative organs to do their utmost, and thus lessen their power of destruction, and at the same time get the patient out of the parturient condition as soon as possible.

The question may arise, Is there a microbe present in all pregnant women, which some are able to throw off and others are not, which in some increase so much as to endanger life?

We firmly believe that this form of eclampsia, with our present knowledge of treatment, is *always* fatal; that the *four* previously mentioned are seldom fatal if the treatment we have suggested is faithfully carried out.

STUDY OF A CASE OF ERYSIPELAS GENITALIUM, DUE TO THE USE OF INFECTED OINTMENT.[1]

BY ADELAIDE WARD PECKHAM, M.D.,
OF PHILADELPHIA.

M. D., born October 7, 1892, was a plump, healthy babe, with fair, sound skin. The navel healed quickly. The mother seemed free from disease, convalesced without rise of temperature, and there was a history of preceding normal pregnancies.

On November 12th, five weeks from the date of birth, I saw the child after an illness of twenty-four hours. The mother said that for a slight "chafing" of the genitalia she had applied an ointment that she had in the house, and that during the following day and night the child had become alarmingly ill.

On inquiry, the mother stated that the ointment had been used by a woman in the family on a suppurating gland in the neck, application having been made by dipping the fingers in the ointment. This woman gave a history of having fallen through a hatchway, striking the side of the neck upon a projection in the wall; a large abscess had formed, which suppurated very freely, leaving a long and angry-looking cicatrix.

On examining the child, the following conditions were found: Temperature, 103.8° F.; pulse full and very rapid, all food vomited, bowels constipated, extremities cold, convulsive twitchings of the muscles of the face and limbs, fingers and toes flexed, the pupils contracted. The child was in a state of coma. Locally there was a small excoriation on the left labium, intense redness and swelling of the skin over the pubic region, which was sharply defined, and did not extend to the anus. On November 13th, the second day, the erythema had extended to the anus and creases of the thighs; the labia were so infiltrated that the skin seemed tense enough to rupture; the temperature was 103.4° F. On November 14th, the inflammation had extended over the lower third of the abdomen and lower half of the back, making a shining, inflamed surface so sensitive that the child had a slight spasm when moved; temperature still 103.4° F. On November 15th, there was no extension of inflammation upward, but it had reached the left knee and halfway down the thigh on the right side, the parts being swollen to nearly twice the normal size; the skin over the genitalia was slightly paling; temperature, 103° F. On November 17th, both legs were very much swollen, and of a dusky-red color. The convulsive movements and insomnia, which had lessened, returned again; the tongue was coated; there was intense thirst and slight diarrhea. The temperature was now 102.4° F. On November 22d, the right foot was swollen, the inflammation on the right side reaching a point two days later than on the left; the cuticle was flaking on the parts first attacked, and on the labia it came off in casts; temperature, 99°. On November 25th, the left foot was nearly normal, and the right improving; temperature, 99° F. On November 29th, there was

[1] From the Laboratory of Hygiene, University of Pennsylvania.

noticed a swelling on the top of the left foot, and another on the inner malleolus of the right ankle showed beginning abscess-formation: there was also edema of the left labium. The temperature was normal. On December 2d, there was slight cough, the first symptom of the broncho-pneumonia that followed. Both abscesses were lanced. On December 8th, the respirations increased in frequency, and an area of dulness was found by percussion on the right side posteriorly; large and small mucus râles were heard over both lungs; there were frequent spells of coughing, with cyanosis around the mouth and nose, relieved by vomiting. On December 13th, another large abscess on the right ankle and a small one on the top of the left foot were lanced. A swelling, the size of a walnut, was found in the anterior axillary line between the fifth and sixth ribs. On December 14th, the rattling respiration and severe cough still continued. The skin over the abscess on the chest began to redden, and the temperature was 100° F. Two small abscesses were lanced, one on each foot. On December 18th, an abscess on the chest was lanced; the lungs were much clearer.

The left leg was red and swollen to the knee on December 21st. The temperature was 100° F. The redness of the leg had disappeared on December 23d, and a swelling involving two lymphatic glands was found in the left groin; these two glands coalesced into a single abscess-cavity. On December 24th, an abscess in the groin was lanced, and two ounces of pus were discharged. On December 26th, an abscess was forming under the right knee, and two enlarged glands were found in the left axilla. On December 27th, the abscess under the knee was lanced; temperature, 99.2° F. On December 30th, the incision made under the knee had become occluded by the dressing; temperature 106° F., but it fell to 101.2° F. in three hours after drainage was reëstablished. A gland in the left groin was much enlarged. On December 31st, the temperature was 100.1° F. A small abscess on the left ankle was lanced. On January 18th, two abscesses in the left axilla and one in the right groin were lanced.

During the whole period of abscess-formation the temperature seemed remarkably low. The test was made at different hours and on each day, and at no time did the temperature exceed 99° F., with the exception mentioned in the history.

Treatment.—During the first forty-eight hours hot fomentations were applied to the inflamed parts. Calomel, $\frac{1}{12}$ gr., with 2 grains of sodium bicarbonate was given every hour until the bowels moved. An ointment containing one dram each of ichthyol and zinc oxid to an ounce of cosmolin was used during the remainder of the attack of erysipelas. During the pyemia, brandy and syrup of iron chlorid were given in suitable doses, and elixir of calisaya whenever there was rise of temperature.

BACTERIOLOGIC STUDY OF THE CASE.

The following experiments were made with the blood, pus, and sputum taken from the child, and with the ointment used during the first twenty-four hours of its illness. The latter was that variety of petroleum ointment named "Lucilline."

EXPERIMENT I.—On November 16th, from the advancing margin of the disease on the leg two drops of blood were drawn by puncture with a sterilized needle, the skin having previously been thoroughly washed in a solution of carbolic acid of approximately 2 per cent. strength. From the drops of blood six slanting tubes of nutrient glycerin agar-agar were inoculated by smearing the blood upon the surface of the culture-medium with a sterilized platinum-wire needle. These tubes were placed in the incubator for twenty-four hours; they then showed a growth of isolated colonies differing in size and color, a pin-point pearly growth being very plentiful. From the different colonies on these tubes a series of Petri plates, four in number, was made, and from single colonies on these plates tubes were inoculated, and pure cultures obtained. By their growth on different media, and by microscopic examination of cover-slip preparations, these proved to be the streptococcus erysipelatis, the staphyloccus pyogenes aureus, and a nondescript bacillus

EXPERIMENT II.—Inoculations were made from the ointment by smearing fifteen tubes of glycerin agar-agar with it, using the amount taken up in a looped platinum wire for each tube. Mixed growths were found on twelve tubes after exposure to a temperature of 37° C. for twenty-four hours. Petri plates were made as before, and from single colonies pure cultures of a streptococcus and the bacillus pyogenes fluorescens were obtained.

Macroscopic comparison was then made of the streptococci obtained from these two sources, regarding their growth on different media and their reactions. Two sets of tubes of the different kinds of media were inoculated, the one with the streptococcus from the child, the other with that from the ointment. The inoculations were made in the same hour and kept in the incubator an equal length of time. The streptococci from both sources were found to be identical in every respect, and we feel justified in thinking the streptococcus in the ointment to be the streptococcus erysipelatis. It presented the following characteristics:

On Petri plates of ordinary nutrient agar-agar, glycerin agar-agar, and gelatin, pin-point, pearly-white colonies are found, which under a low power of the microscope are round, finely granular, of a yellowish-brown color, with even edges. Smears on agar-agar, glycerin-agar and gelatin, show macroscopically a delicate, pearly growth, with many isolated colonies, growing most luxuriantly on glycerin agar-agar, and least on gelatin. They do not liquefy gelatin. On potato the growth is invisible, but after a short time there is an increase of moisture about the point at which the organisms were deposited. In neutral or slightly alkaline litmus milk it causes a very faint pink color in twenty-four hours; this change in color is not due, apparently, to any production of acid, as the reaction of the milk, even when this color is present, is shown by litmus and curcuma paper to be slightly alkaline,

and remains so for several weeks. In none of a number of experiments bearing on this point was there any coagulation of the milk, or any deviation from the change in the reaction described. In deep stab-cultures (8 cm. deep) there is a growth along the entire track of the needle, as well as upon the surface. This growth is most luxuriant at the temperature of the incubator, 37° C., and also develops, but less rapidly, at ordinary room-temperature. This organism stains readily with the ordinary anilin dyes.

Microscopic examination of fresh cultures, especially in bouillon, show the cocci arranged in long chains. Similar long chains are also to be found in blood-serum cultures; upon other solid media chains are likewise to be found, but they are usually shorter.

EXPERIMENT III.—Experiments upon animals gave the following results:

Two rabbits were inoculated, one intra-venously, the other by scarification on the ear, with pure cultures of the streptococcus of the fifth generation. An area of slight inflammation found at the point of inoculation on the third day soon disappeared, and no further result was obtained. Two rabbits were again inoculated in the same manner with a culture of the first generation. The experiment proved negative.

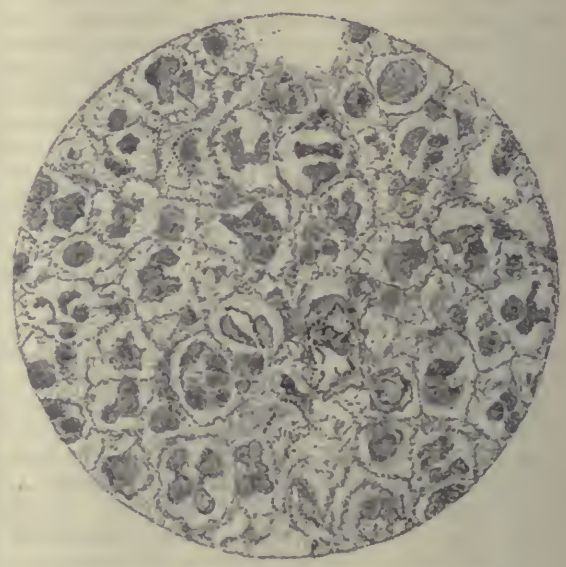
EXPERIMENT IV.—To determine whether the ointment was free from bacteria when procured, the outer portion was removed, and from the deep part ten tubes of glycerin agar-agar were inoculated as before. The tubes were inoculated December 1st, and have remained sterile up to the present time (January 15th).

EXPERIMENT V.—To prove that the bacteria would live in the ointment, test-tubes containing ointment were sterilized for two hours, the ointment allowed to harden in slants, and inoculated with the streptococcus erysipelatis, the staphylococcus pyogenes aureus, and the bacillus pyogenes fluorescens, the cultures used being of the fifth generation from the patient. From these tubes inoculations on glycerin agar-agar were made every third day, and cultures of the organisms introduced obtained for twenty-one days. Cultures of streptococci were obtained from the box of ointment for forty days, and the bacillus pyogenes fluorescens is still easily obtained after sixty days.

EXPERIMENT VI.—In the first stages of the broncho-pneumonia, tubes were inoculated from the sputum. The staphylococcus pyogenes aureus was obtained, but the streptococcus, if present, was not found.

EXPERIMENT VII.—After the twelfth abscess, tubes of glycerin agar-agar were inoculated with blood taken at a point farthest from any abscess; no growths were obtained. Tubes were then inoculated with blood taken from near an enlarged gland, and colonies of the streptococcus appeared in twenty-four hours. Cover-slip preparations of blood from the same point showed a very few diplococci and marked leukocytosis.

The pus from the first abscess was examined microscopically. A stained cover-slip preparation (Löffler's blue) showed streptococci in short and in long entwined chains, and, throughout the specimen, solitary scattered diplococci. Some of the leukocytes contained short and entwined chains of streptococci, as shown in accompanying illustration. The cells were mostly polynuclear leukocytes, some of which showed various stages of nuclear division. A few cells contained small stained granules of a purplish tint. No other bacteria were found by using different stains, and from Petri plates inoculated with pus only pure cultures of streptococci were obtained. The pus from each large abscess was tested in the same manner with the following result: Pure streptococci were obtained in every case, with one exception, in which a skin coccus, the staphylococcus epidermidis albus, was isolated.



SUMMARY.—The points of interest in studying this case are the following:

1. That bacteria were conveyed from one person to another through the intermediation of an ointment.

2. That the streptococcus erysipelatis lived forty days in an ointment.

3. That streptococci taken directly from the point of suppuration lived longer in ointment than those which had passed through several generations on media.

4. A typical case of erysipelas genitalium, having been caused by a streptococcus from a suppurating gland, with no known preceding lesion, tends to confirm the opinion that the streptococcus pyogenes and the streptococcus erysipelatis are identical.

5. Streptococci were found in the blood.

6. The necessity of antisepsis, even in pyemia, is shown by this case. The abscesses were due to streptococci only, and precautions were necessary to prevent mixed infection by the introduction of

the staphylococcus pyogenes aureus found in the skin and sputum.

NOTE.—The condition of the child at the time of writing points to recovery. The fourteenth abscess has just been lanced. Those that have formed within the past two or three weeks have matured slowly, and the child has gained in flesh and strength. The digestion, which has been fairly satisfactory during the entire sickness, is good. Anticipating a fatal issue, promise of autopsy was obtained, and should death finally occur, a protocol of the autopsy will be added to this article.

In conclusion the writer extends thanks to Dr. A. C. Abbott and Dr. A. A. Ghriskey for direction and verification of work.

ORIGINAL ADDRESS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

The Inaugural Address of the President, delivered at the Eighty-seventh Annual Meeting, February 7, 1893.[1]

BY L. S. PILCHER, M.D.

Members of the Medical Society of the State of New York:

THE people of this Commonwealth, by the act of their representatives in the Legislature of 1806, constituted this Society the legal representative of the medical profession of the State, provided for the organization of the practitioners of the State into county medical societies, and by a later enactment made it the duty of every physician to join the medical society of his county. To these societies were committed important functions pertaining to the licensing of medical practitioners and to the regulation of the practice of physic and surgery, while they affiliated with and were subordinated to the State Medical Society.

With the lapse of years the development of new conditions of society, of education, and of practice, brought from time to time modifications in the duties presumably required of these medical corporations. The function of supervising the qualifications of those who should desire to practise physic and surgery in the State of New York was virtually abrogated by the law of 1844, which threw open the privileges of medical practice to all men who could protect themselves from suits for damages due to malpractice, from ignorance, or immoral conduct in their practice. The Legislature of 1857 gave legal status to practitioners of homeopathic medicine by incorporating them into State and county societies, and likewise in 1865 the eclectic practitioners were given a similar legal status.

In 1874, 1880, and 1887 statutes were enacted by the several Legislatures of those years, regulating and defining the status of the medical practitioners in the State, by which the prerogatives of the State and county medical societies were less prominently acknowledged, and the importance of chartered medical colleges was more clearly recognized. Nevertheless, throughout the whole of this long period of eighty-seven years the State of New York has never ceased to recognize the dignity and importance of the Medical Society which it created in 1806 as the proper representative and exponent of rational medicine within its borders. This Society has ever been unceasing in its efforts for the public welfare, for raising the standard of medical character. By virtue of its representative character, of the loftiness of its aims, and the personal dignity and worth of its members, its influence for good in this Commonwealth has never been measured or restricted by the legal regulations or stipulations that may have bound it at any period of its history. It has, furthermore, continually used its influence to elevate the status of medical education and practice throughout the country at large. During the early years of its history it was active in securing common action among the medical colleges of the United States in improving the character and extent of the teaching in those institutions; later, it inaugurated and carried to a successful issue the movement for organizing an American Medical Association; and in the more recent past, it did not hesitate to declare that with the changing conditions of knowledge, of education, of legislative enactments, and of social conditions, it was desirable that the medical profession should emancipate itself from certain paternal restrictions that it had inherited from the conditions of a previous generation, and to formally take action giving a large liberty of personal judgment upon ethical questions to all who acknowledged its authority. It thus placed itself again in the forefront of a reform the effects of which have spread far beyond the limits of the State within which this Society has any jurisdiction.

In the immediate present, the Commonwealth has again intrusted to this Society the important duty of supervising the qualifications of all who may hereafter desire to practise rational physic or surgery within the State of New York, by the recent law constituting a medical Board of Examiners, whose members shall be nominated by this Society, and to whom, thus representing this Society, and being accountable to it for their work, is committed the prerogative of fixing the standard of educational qualifications to which every future practitioner of rational medicine in this State shall attain before receiving license to practise.

Your President has taken pains during the past year to acquaint himself with the condition of the medical profession throughout the State. The estimated number of practitioners is 10,000; the estimated population is 6,000,000—or one physician to every 600 of population; of these 10,000, about 8000 are practitioners of rational medicine, 1300 of homeopathic medicine, 400 of vegetable medicine, and the remaining 300 represent many kinds of medical theories.

The number of schools devoted to undergraduate instruction in rational medicine is 9: of these, 2 are in the city of Buffalo, 1 in the city of Syracuse, 1 in Albany, 1 in Brooklyn, and 4 in New York City. 2096 students are at the present time under instruction in these schools: 128 in Buffalo, 58 in Syracuse, 170 in Albany, 201 in Brooklyn, and 1539 in New York City.

The number of schools in the State of New York de-

[1] The exigencies of our space do not permit us to publish this able address in full, but we reproduce all that pertains to general or national medical questions.—ED. NEWS.

voted to post-graduate instruction is 2, both in New York City. During the past year the number of matriculants at these two schools has aggregated 819.

The number of students in the medical schools in this State is especially significant from the fact that the entrance into these schools is guarded by a preliminary examination prescribed by the State and conducted, not by the officials of the schools, but by the Board of Regents of the University of the State—an examination which is not a mere form, but is sufficient to insure that intending students of medicine shall already possess a fair general education before beginning their technical studies. It is still more significant from the fact that the diplomas of these schools no longer confer the right to practise medicine in the State of New York, and have value only as the thoroughness and comprehensiveness of the instruction to which they testify are acknowledged by public opinion. The laws of the State now require that all who hereafter enter upon the practice of physic or surgery in this State shall have attended three full courses of lectures, and all the medical schools of the State now require the same amount of attendance upon lectures before the granting of a diploma, while the general influence of these teaching bodies is to encourage their students to extend their periods of lecture-attendance to four years. The influence of the present conditions that attend medical education in this State is very healthful, in that every teaching corporation is directly stimulated to improve its methods and facilities for teaching, that thereby students may be attracted to its halls.

An examination of the curriculum and the published statement of each of the schools of this State, supplemented in some instances by additional statements from the dean, shows that much has been done already, and more is contemplated in the immediate future, toward securing proper gradation of studies, division of students into small sections under tutorial supervision, systematic text-books and laboratory drill, and adequate personal contact of the students with patients in dispensary and hospital classes. The present law of the State with regard to the supply of anatomic material is fairly liberal, and an enlightened public opinion has sustained its practical application whenever it has been brought into question. Laboratories of histology and pathology have been furnished and equipped in connection with all the schools, and in New York and Brooklyn elaborately planned and fully endowed institutions for these departments of instruction exist, in which not only the instruction of students is provided for, but every facility and encouragement for original work is furnished, not only to their staff of instructors, but to any member of the medical profession.

The department of practical obstetrics presents conditions of special difficulty in American communities for organization so as to give the needed amount of practical demonstrative teaching to students. Appreciating this, and thinking that this one department might be taken as a fair index of the average character of the instruction that was being given in the medical schools of the State, I addressed to each of them an inquiry as to the amount of practical experience in midwifery required by each of the students before graduation, stating that I intended to present the information thus obtained to this Society. The following are the answers received:

Medical Department of Niagara University: Each student attends from five to ten cases before graduation.

Medical Department of the University of Buffalo: Each student is required to attend at least two cases.

Medical Department, Syracuse University: At least one case must be attended; usually from two to four are given.

Albany Medical College: Provision is made to enable members of the senior class to attend one or more cases of obstetrics.

Long Island College Hospital: All obstetric cases in this hospital and in Kings County Hospital are used for clinical instruction. Six students in the former and three in the latter attend each labor. The number of labors attended by each student has varied from five to fifteen.

Woman's Medical College of the New York Infirmary: Each student is required to attend ten cases.

Bellevue Hospital Medical College: Each student is recommended to have a two-weeks course at the Midwifery Dispensary, during which he attends at least six cases of labor, but this is not obligatory.

Medical Department, Columbia College: Every student is required to attend the Sloane Maternity for one week, day and night; to examine all cases and to be present at all confinements.

Medical Department, University of the City of New York: Students who desire it may secure attendance in the lying-in service of the Midwifery Dispensary for periods of two weeks or more; this is not obligatory.

From these replies it is evident that much progress is being made in this most important department of medical instruction. It appears, however, that in at least two of the largest schools in this State it is still possible for students to receive the degree of Doctor of Medicine without ever having seen a case of labor. I know that it is the desire of the authorities of these schools that at the earliest practicable moment this reproach should be removed, and I submit that it is a proper thing for the Medical Society of the State of New York to use its influence in promoting this end. For this purpose I would recommend that this Society formally request the Regents of the University of the State to decree that an essential requirement for admission to an examination in obstetrics by the State Board of Medical Examiners shall be that the candidate certify to having attended at least three cases of labor.

Time does not permit me to further analyze the methods of medical education now prevalent in this State. I think, however, that all the facts warrant the statement that positive improvement in every direction is constantly being effected, that it has already attained a breadth and thoroughness and practical value that compel the confidence of an enlightened public, and that wherever deficiencies or occasions for adverse criticism still exist, they will gradually be removed with the lapse of time; they are the faults of youth, the results of the absence of governmental control and endowment, the effects of the spirit of individualism which is at once our pride and our weakness. It will ever remain the duty of this Society to point out the way of improvement and to give form to the public and professional opinion that must precede each advance step.

The State Board of Medical Examiners. The work of this Board may now be considered as fully inaugu-

rated. The time during which any persons desiring to practise medicine in this State were exempt from examination by this Board has now elapsed, and at the present time the only gateway to the legal practice of medicine in this State is examination by this Board. I am not aware that the two years of testing to which this law has been subjected has shown it to possess any objectionable features, while its influence is acknowledged by all to have been beneficent. Up to the first of December last, 90 candidates had been examined by the Board representing this Society, of whom 80 had been accepted; 10 by the Board representing the Homeopathic Medical State Society, of whom 5 were accepted; and 5 by the Board representing the Eclectic State Medical Society, of whom 2 were accepted. When it is remembered that these were all subjected to the same examination, except in the department of therapeutics, it illustrates the direct effect of the bill on the public welfare—since, while it caused the rejection of 11 per cent. of the candidates from the schools of rational medicine, it caused the rejection of 50 per cent. and 60 per cent. of the candidates from schools of sectarian medicine. The inevitable result of the continuance of the work of this Board will be to greatly improve the general standard of medical education in this State. It is certain, also, to excite the antagonism of those whose pretensions are put in so bad a light by its workings. It behooves every intelligent and public-spirited citizen to protest on every proper occasion against any modification of the existing law which shall weaken its force or efficiency in any way. It would be proper for this Society at this time to adopt a resolution expressing satisfaction with the law as it now stands, and requesting that the Legislature decline to permit any modification of its provisions, for the present at least, and instructing its Committee on Legislation to be vigilant in guarding this law against amendment or attack. I accordingly recommend such action to the Society.

The American Medical Association. I have the pleasure of presenting to the Society at this time a communication from Dr. Wm. B. Atkinson, permanent Secretary of the American Medical Association, transmitting a resolution adopted by that Association at its session held in Detroit, June, 1892, appointing a committee of five, instructed to meet a like committee from the State Medical Society of New York, and the State Medical Association of New York, for the purpose of adjusting all questions of eligibility of members of the State Medical Society of New York to membership in that Association, and notifying this Society that the committee in question had been appointed, consisting of Drs. N. S. Davis, of Illinois; John H. Rauch, of Illinois; Wm. T. Briggs, of Tennessee; Dudley S. Reynolds, of Kentucky, and Willis P. King, of Missouri.

The evident intention of this resolution was to request that this Society appoint a similar committee to confer with the committee named, although the resolution as transmitted does not say so. It is difficult to see what purpose such a conference as is proposed could serve. The American Medical Association is very properly its own judge of what shall be the qualifications required of its members. It is a voluntary association, responsible to no one, and may change its standard for admission at its will. At its session in St. Paul, in June, 1882, it voted that the Medical Society of the State of New York was not entitled to representation in it because the Code of Ethics adopted by that Society essentially differed from and was in conflict with the Code of Ethics of the American Medical Association. The status of affairs to-day differs in no respect from what prevailed in 1882, save that a year or two later the American Medical Association adopted an explanatory declaration which practically interpreted its own code to mean the same as the code already adopted by the Medical Society of the State of New York. It did not, however, rescind the vote of disfellowship adopted in 1882, but on the contrary, at the recent meeting in Detroit, renewed it, and extended it to embrace not only this Society as an organization, but also all persons who affiliated with it. At this same meeting, also, it appointed a committee to report upon the revision of its own Code of Ethics. There is, therefore, no certainty as to what the future Code of Ethics of the American Medical Association will be. It would be highly improper for the Medical Society of the State of New York to assume in any way to dictate to, or even suggest to any organization not subordinate to it, what ethical standard, if any, such an organization should adopt. It must content itself with regulating its own standards, as it now does, suggesting in turn that it is equally indelicate for organizations that have no supervising relation to it, to extend advice as to its internal affairs. Practically, the relations of the Medical Society of the State of New York to the American Medical Association are the same as those which it sustains to the British Medical Association, the Canadian and Ontario Medical Associations, and to the medical societies of the various adjacent States to which it is in the habit of sending delegates annually, viz.: the relations of courtesy and comity. All of these medical organizations named continue to receive with due honor and respect the delegates appointed by this Society, and, doubtless, whenever the American Medical Association shall signify its desire that this Society shall again send delegates to its meetings, such delegates will be sent. The Medical Society of the State of New York, however, must meanwhile be content to do its own work in its own way, awaiting the pleasure of the Association in question. Nevertheless, since a failure by this Society to appoint such a committee as is contemplated in the communication from the American Medical Association would doubtless be construed by many, who are still ignorant of the real relations that exist between the two organizations, as displaying a factious and quarrelsome spirit, and as a matter of simple professional comity I would advise that a committee of five be appointed by this Society to meet the committee of the American Medical Association as requested.

The Code of Ethics. In the course of the discussions which have been provoked by the action of the American Medical Association just alluded to, it has come to the knowledge of your President that many of the physicians of this State are convinced that, in view of the present state of general enlightenment prevailing throughout the State of New York, and the safeguards which by legal enactments are thrown about the entrance into the medical profession, it would comport more with the dignity of the medical profession, and would enhance the respect in which it is held by the general public if all

specific rules of ethical conduct were elided from the By-laws of the State Medical Society, and if the regulation of such matters were hereafter left to the judgment of individual practitioners influenced by the well-known consensus of professional opinion and local custom in the places where the work of each is being carried out. Among a large number of representative physicians from all portions of the State with whom I have conferred on this point, I have found a singular unanimity of feeling on this subject. The only hesitancy which any have expressed has been as to whether it would be wise, since practically this is already the present status of the profession in this State, to make any movement looking to a formal elision of a code from our By-laws, lest it should revive acrimonious discussion, and reawaken strife that would be detrimental to the higher interests of the profession in this State. By far the greater weight of the opinions which I have been able to elicit has, however, been that no such result would follow, but that, on the contrary, such action would tend still more to heal old differences and bring together all the elements of the medical profession in this State. Such is also my own mature opinion; and, further, it has seemed to me that at present, when there is a general revival of interest in the matter of professional ethics—as is evidenced by the discussions which are now going on in the medical journals of the country—and when this question of code is again unavoidably brought to the attention of this Society, it is a specially favorable moment for taking this final step. At the present time the only allusion in the By-laws of this Society to a system of medical ethics is the very brief Section 8 of Chapter VI, which merely says:

"The system of medical ethics adopted by this Society, February 7, 1882, shall be considered authoritative to govern the medical profession in the State of New York."

I would recommend that this section be dropped *in toto*. The effect of such action would be to leave this State Society without any formulated Code of Ethics, and to relegate the code of 1882, together with those of 1847 and 1823, to the domain of history, though ever remaining of interest and value to the student of the development of ethical standards in the medical profession of this State.

A National Quarantine. Prominent in the thoughts of both physicians and people at this time are considerations as to safeguards against the invasion of this country by cholera, the danger of which all the lessons of the past warn us is imminent. Action has already been taken by many of the county societies of this State urging upon Congress the enactment of comprehensive laws establishing the national regulation of quarantine. Doubtless at an early period in this meeting this subject will engage the attention of this Society and will receive thorough consideration at your hands.

It is to be hoped that Congress will not be satisfied with hasty legislation intended only to meet a present emergency, but that it will forthwith institute a committee of inquiry that shall thoroughly investigate and consider all matters pertaining to national sanitation, which shall mature a report that shall result in the enactment of permanent and comprehensive laws in this department of the public welfare.

ORIGINAL LECTURE.

RELAPSES OF TYPHOID FEVER.

Part of a Clinical Lecture,
delivered at the Pennsylvania Hospital, January 14, 1893.

BY PROF. J. M. DA COSTA, M.D., LL.D.

[Reported for THE MEDICAL NEWS.]

GENTLEMEN: The next case to be brought before you this morning is one of relapse of typhoid fever. Now, gentlemen, relapses following typhoid fever are in themselves an interesting study. They are of interest, in the first place, because you can never know in a case of typhoid fever when a relapse may happen; there is nothing to distinguish the cases from other cases until after the beginning of the relapse. They are of interest, again, because the relapse gives us symptoms somewhat different from those of the original attack. They are also interesting from the fact that the causes of these relapses are exceedingly difficult to understand, and of great importance to study. Therefore, besides their clinical interest, they possess a pathologic interest which is inexhaustible.

Now, to prove to you the character of this case, before we examine into his condition this morning, I shall briefly indicate the principal points in his clinical history. He is a young man, nineteen years of age, admitted on the 13th of December, suffering with typhoid fever. He stated that previous to his admission he had been ill for about twenty days. I do not know that this is altogether true. By this I mean that he was not in a condition, when admitted, to give a very clear account of his previous history.

What makes me doubt the statement that he had been suffering with typhoid fever for three weeks is the temperature-record that has been kept since his admission. It begins with 104° F. on the afternoon that he was brought here; it remains very high, or in the neighborhood of 104° for three days; it then commences to zigzag, with rather a high evening temperature (103.1°) until we find it down one morning to 99.5°. This low temperature, it is noted, followed free cold sponging, and was only temporary, for it again rose to 102° in the evening. This is the temperature-record of the first week, or a little beyond. In the second week we notice the same continued fever-temperature, which, though still above the normal, does not exceed 102°; and so it goes on into the third week, when, slowly and with considerable variation between higher evening than morning temperatures, it descends to normal. On the 24th of December, he is free from fever. This is the temperature-chart, or fever-record, of the man while under treatment in the hospital; this is what makes me doubt that he had been sick for twenty days before coming here. He has probably included his prodromic symptoms in the time of his actual illness, which probably had only existed for four or five days prior to admission, judging from the subsequent course of the fever.

With regard to the original attack of typhoid, I merely observe that it was not accompanied by anything decidedly out of the way. He had very little intestinal disturbance; if anything, the attack was marked by its

freedom from such disorder, as the bowel-movements were not frequent, not more than two or, at most, three in a day. There were very few spots; very little tympany—in truth, the case was regarded as a mild one; he was never delirious, and slept well at night; there were no marked nervous symptoms.

Now, gentlemen, I have brought this man before you this morning to show what has occurred since the 24th of December, when he had a normal temperature and was convalescent. The temperature was even subnormal during the following week, for the morning observations are from 97° to 98°, with slight evening rise, which is common after typhoid fever. So it goes on until the 8th of January—six days ago—when the morning temperature was 98.6°, and the evening temperature 103°. On the next morning, it goes down only a little over half a degree (102.4°), and then, on the second day of this relapse, his evening temperature is 105.4°. Here is the record which is so significant! Observe the normal, or slightly subnormal, temperature for two weeks, then this marked rise. Now mark the course afterward. The morning after this exacerbation the temperature goes down to 100°, largely as a result, I believe, of a cold bath and repeated sponging with water under the care of our attentive nurses; but it does not stay down; it goes up the next evening to 103°, yet by repeated cold spongings it was reduced again to 100°. After this there is a solitary rise to 103°, but in the main the temperature is kept down by continuing these cold applications, and by another plunge-bath.

Now, you wish to know something about the other symptoms. When the relapse began he had epistaxis of two or three days' duration. His mind was quite as clear as during the original attack, although his temperature was above 105°. He complained, it is true, of some headache, which lasted two days and occurred at the same time as the epistaxis; but there was no delirium, no restlessness, no jerking of the tendons.

Having shown you the temperature-record and having noted the absence of nervous phenomena during the relapse, we turn to the intestinal symptoms. What were the intestinal lesions, as interpreted by the symptoms? He had three or four loose movements during the day, more, you observe, than during the original attack. His tongue has been slightly coated and dry; it is a little cracked at the edges and tip. There have hitherto not been any spots noticed, but I observe one or two rose-spots upon the abdomen to-day, which have appeared since yesterday. In his first attack he did not have many spots, and, in truth, after the first day or two we found no spots. These that we see here have, as stated, just appeared. It is true that a general duskiness of the skin makes this case unfavorable for the detection of the characteristic spots, but careful inspection failed to detect them until this morning.

To complete these notes, I will add that he has also some enlargement of the spleen; the splenic dulness begins a full finger's-breadth below the ribs. He has no albumin in his urine. Upon auscultation we find a very short, almost inaudible first sound and a very sharply defined second sound, but without murmurs.

These are the symptoms, gentlemen, in this case of relapse. Now, I shall proceed to the interpretation of these phenomena, by pointing out the symptoms that indicate a relapse of typhoid fever; and, on the other hand, the difference between the symptoms of the relapse and those of the first attack.

The most marked symptom, in the first place, is the temperature. In typhoid fever the characteristic feature is the course of the fever,- the gradual ascent of the temperature during the first week, with the evening rise and the morning remission, but each evening higher than the previous day, until the fever reaches its highest point in the second week. This feature is not shown in the relapse. We have seen that the morning temperature of January 8th was 98.4°; in the evening it was 102.4°; then with this morning remission of half a degree, in the evening of the second day we have the highest temperature that has been attained in the case, 105°. This is entirely unlike the history of ordinary typhoid fever. A peculiar feature of the relapse, thus, is the rapid ascent of the temperature. In this case, I repeat, it attained, on the second day of the relapse, the highest point that it had reached in the whole course of the disease. Subsequently, instead of descending by degrees, as in an ordinary attack, it descends rather abruptly, and has no regularity in its return to the normal.

Then we have the re-development of the intestinal symptoms; the enlargement of the spleen; the reappearance of the spots. In reference to these spots, I would say that their appearance so late as the sixth day of the relapse is not common. They are usually an early symptom, coming out on the second or third day. In the original disease, you know that from the seventh to the ninth day is the usual time for the eruption of these rose-colored spots. In this case the relapse does not differ so much as in other cases, for very generally in relapses of typhoid fever the spots appear much earlier than in the original attack, and this furnishes a diagnostic point.

The nails will hereafter show a distinct ridge of altered nutrition to mark this relapse, but at present they show nothing, except a loss of natural polish. The appearance of a ridge upon the nail, as the result of the attack of typhoid fever, will be followed by a second ridge, indicating the occurrence of the relapse. I will bring him again before you after a few weeks, and you will then be able to distinguish these marks of the disease through which he has recently passed, and from which he is convalescing.

It may be asked, "Is there danger in these relapses?" Do the intestinal lesions or typhoid ulcers break out afresh? Yes, we may have fresh ulceration and hemorrhage, which may be fatal; but it is a curious circumstance that the intestinal lesions that are developed during the relapse run a much more rapid course (just as the fever runs a much more rapid course) than in the primary outbreak. As a rule, however, the intestinal symptoms are less grave. The duration of the relapse is usually about nine days, while that of the first attack is three or four weeks, The ulcers run a more rapid course, and cicatrize earlier; therefore, they are not so dangerous as in the original attack of typhoid fever.

Does this relapse end the whole case, or may there be subsequent relapses? Gentlemen, it has been my lot to see two cases, each of which had five relapses; therefore, they survived six attacks of the disease. This

sounds incredible, but I have the temperature-charts that prove it. Both cases are still living. Therefore, relapses are in themselves not necessarily so dangerous to life as one might think. It is bad fortune, certainly, for a patient to have a number of relapses: a man usually considers himself very unfortunate to have a single attack, and doubly so to have a relapse when he thinks that he is convalescent, and begins to congratulate himself upon his return to health; and he is more unfortunate still to have several.

I want to call your attention particularly to the fact that you may have intestinal hemorrhage in this relapse, and to the importance of being on the look-out for it. The necessity of keeping the patient absolutely at rest, and carefully regulating his diet, will be manifest.

As to the causes of the relapses, they are usually believed to be due to indiscretion in diet; but I am of the opinion that this is not the cause. When I was first visiting physician to this hospital, I always, in these cases of relapse, had the forbidden apple or pie diligently searched for, but I must confess that I rarely found it. Indiscretions in diet will, undoubtedly, cause diarrhea; but they will not cause a return of all the phenomena of typhoid fever. Relapses are not due to indiscretions in diet. To what, then, are they due? I can only offer you a probable explanation. It is supposed that the specific germs of the original attack remain in the intestinal tract, and the patient poisons himself by these germs, and the poisoning may take place several times. This theory of the reappearance of the symptoms after the orignal attack has passed is in harmony with the prevailing ideas, which attribute the causation of typhoid to a specific bacillus, which is present in the intestine during the whole course of the disease, and may persist for an indefinite time after apparent recovery.

As regards the treatment, it is the same as in the original attack. The same regulation of diet (principally or exclusively milk); the same precautions as regards the general management as in ordinary typhoid fever; the same measures to allay irritability and promote an antiseptic condition of the intestines, should be adopted; and in the relapse they are even more essential. In the original attack he took naphthalin, and as he has still some diarrhea, we will resume the naphthalin (gr. ij every three hours). To this will be added a little opium (a teaspoonful of paregoric), when the bowels are too frequently moved. There is nothing to say with reference to the treatment other than would be said about the original attack. The case is instructive as showing the phenomena of relapse coming on without warning during apparent convalescence.

The Treatment of Syphilis.—Accepting the dictum that in the treatment of syphilis with mercurials it is the mercury that constitutes the active agent, McNAMARA (*Lancet*, No. 3617, p. 1438) maintains that the best preparation to use is that which in safe, unirritating doses contains the largest proportion of the metal. This indication he has found to be best met by mercury with chalk, of which an adult may take a grain or two grains three times a day, with a grain or more of the powder of ipecac and opium if there be diarrhea. The treatment should be continued for some months.

CLINICAL MEMORANDA.

TWO CASES OF MEMBRANOUS ENTERITIS.[1]

BY S. SOLIS-COHEN, M.D.,
PROFESSOR OF CLINICAL MEDICINE AND APPLIED THERAPEUTICS IN THE PHILADELPHIA POLYCLINIC; ONE OF THE PHYSICIANS TO THE PHILADELPHIA HOSPITAL.

THE essential clinical feature of the condition best known as croupous enteritis, or membranous enteritis, is the discharge from the bowel of mucoid, fibro-mucoid or fibrinous casts; the essential pathologic feature being, of course, the formation of these casts.

The affection is not common, yet, as Da Costa,[2] in his classic study long ago pointed out, it is hardly one to which the term rare may strictly be applied. I have encountered some half-dozen cases in the course of ten years. Two of these were in young hysterical females, not my patients, whom I saw on a few occasions, in the absence from the city of the attending physicians, and at the request of the latter. One patient was a middle-aged and hysterical woman, who presented herself at the medical clinic of Jefferson Medical College Hospital, during my service as chief assistant; the fourth case was likewise that of a middle-aged and hysterical woman, who applied for treatment at my dispensary service in the Philadelphia Polyclinic. (The early records of this clinic were unfortunately lost or mislaid in moving to the new hospital building, and I have no note of the case except in my index of diagnoses.)

Specimens of the discharge from the two other cases are presented this evening. Both patients are males and the cases present sufficient interest to be placed on record.

CASE I. *Membranous enteritis simulating perityphlitis.*—D. W., thirty-three years old, a blacksmith, was sent to my colleague, Prof. J. M. Baldy, at the Philadelphia Polyclinic, by Dr. G. A. Beck, of Danville, Pa., with a request to place him under the care of a medical clinician; and by Dr. Baldy referred to the medical ward, then under my care, February 29, 1892.

From the letters of Dr. Beck and the notes taken by Drs. Gibbon and Knipe, resident physicians, the following account of the case is condensed.

About three years ago the patient began to suffer with severe pain in the hypogastric and right iliac regions. The pain occurred in paroxysms, lasting at first an hour or two; afterward, with slight intermissions, for several days; the intervals between the attacks varying from about a week to so long as two months; the severity progressively increasing.

No information could be obtained as to the character of the discharges prior to August, 1891. At that time a paroxysm of such severity occurred that it was necessary to administer hypodermatic injections of morphine; and the patient was confined to bed for six weeks. The location of the pain, and a tumefaction observed in the right iliac region, aroused the suspicion of perityphlitis, which, however, the subsequent course of events did not verify.

---

[1] Read before the Philadelphia Pathological Society, January 26, 1892.

[2] Amer. Journ. of the Med. Sciences, October, 1871, p. 325.

There was passed by stool "something resembling the trachea of a chicken, followed in a few days by something much resembling a piece of intestine; each was about three inches in length. There was no fever and but little gastric disturbance; a tendency to constipation was noted." For some time afterward membranous shreds and casts continued to pass, the discharge being preceded by constipation and paroxysms of colic. The stools did not contain blood.

After this attack, dull pain in the iliac region was constant, but not so severe as to prevent sleep. Paroxysms recurred at intervals of from one to six weeks, and lasted with remissions for one or two days. At their height morphine had to be given. With the passage of membrane the pain moderated, and with its disappearance, the pain ceased. The patient continued in robust health; his family and personal history were devoid of pathologic significance.

On admission the patient was a robust, well-nourished man, presenting nothing abnormal to physical exploration. He complained of a dull pain in the right iliac region, which was not sensitive to pressure. He had not had a stool for a few days. An enema of turpentine (f℥j) and magnesium sulphate (℥j) in warm water and soap-suds (Oij) was ordered to be given nightly. The hardened feces, and later the unformed fecal material, thus brought away presented nothing noteworthy.

On March 2, 1892, the patient complained of an increase of pain in the right iliac fossa, which was now sensitive to pressure; and a peculiarly sensitive spot was found in the location known as McBurney's point. There was impairment of resonance over a somewhat irregularly pear-shaped area in the situation of the cecum, and to palpation a sense of doughy induration was given.

On March 4th, at 5 A.M., the patient was awakened by griping pain beginning to the right of the umbilicus and extending into the right iliac region. Somewhat relieved by hot stupes, it persisted until 7 A.M., when, with much straining, a stool was passed, consisting of unformed feces and fragments of mucous and membranous casts. The enemata were continued, but brought away no more membrane, only unformed feces and strings of mucus. Slight tumefaction in the right iliac fossa persisted.

The patient was free from pain for six days, when, at 10 P.M., pain, less severe than on the previous occasion, began, as before, at the umbilicus and radiated into the right groin, causing retraction of the right half of the scrotum. The tumefaction was observed to increase, and the abdominal muscles became tense. In about three hours the paroxysm terminated, with the discharge of a small quantity of softened feces with much more mucus and membrane than in the stool of a week earlier. There was much straining at stool. With the passage of the membrane, abdominal tension relaxed, pain ceased, and the tumefaction became much less marked.

Three days later intermitting attacks of sharp shooting pain occurred for about an hour in the forenoon, and recurred at 3 P.M., lasting for about half an hour, when membrane was passed in a few fragments aggregating two inches by two inches, and the pain ceased. On the following day nothing abnormal could be found on abdominal exploration.

Four days later the membrane presented was passed, without straining, after the enema. It is flat, thick, tough, white; toughness and whiteness having become more marked since placing it for preservation in diluted alcohol. The patient complained of dull pain in the hypogastrium, and of slight vertigo. From this time forward no unpleasant symptom occurred and no membrane was passed. As the patient could not be assured that no attack would occur in the future, he was about two weeks later discharged at his own request.

Drs. Coplin and Bevan examined the membrane passed March 4th and March 10th. They report that "the casts are made up almost entirely of fibrinous exudate in which are found large numbers of leukocytes and epithelial cells. From the mucous surface at some points will be found evidence of the sloughing of the mucous membrane. There are also evidences of young bloodvessels in the membranous casts. In some points hemorrhage has taken place."

These appearances seem to point to the fact that the process is, in part, inflammatory, leading to the formation of a pseudo-membrane, which becomes partially organized and then separates by a superficial necrosis. Whether the tumefaction in the right iliac region was due to obstruction of the cecum or colon by accumulation of the products of desquamation, or whether the seat of the morbid process was thus indicated, I do not pretend to say. The size of the casts, however, would indicate their formation in the small intestine.

CASE II. *Pseudo-membranous enteritis in a lithemic patient presenting symptoms of vasomotor ataxia* — X. Y. Z., an attorney, about thirty-two years old, has suffered for some two years, following a great grief, with symptoms termed by various American and European clinicians of eminence as those of "gastric catarrh," and of "neurasthenia." There are in his case some important features not relevant to the present communication, except that they indicate a highly neurotic constitution. When I saw him some four months ago, he was much emaciated, obstinately constipated, passing small quantities of urine of high specific gravity, containing uric acid, urates, phosphates, and oxalates in excess, red blood-cells, no albumin, no sugar. This oliguria was doubtless due to the dry diet advised by a former attendant, as it soon disappeared when a normal quantity of water was taken; though the uric acid, urates, oxalates, and hemocytes did not disappear until appropriate treatment had been continued for some time.

The man's sickness began with frequent attacks of vertigo, which had incapacitated him for the duties of his profession; his circulation was poor, so that hands and feet were almost constantly cold; and just before one of his "spells" the lips and nails became blue, the skin of hands and face pallid. I was summoned while he was suffering with a paroxysm of abdominal distress which he said could not be called "pain" or "colic," though he knew no other term by which to describe it. It had ceased when I first saw him, about two hours later.

I cannot say what excited the suspicion of membranous enteritis; probably it was the hypochondriasis, the constipation, and the evident intestinal spasm. At all events, failing to elicit a history of the passage of casts, the patient was asked to observe his stools; nightly

enemata of warm water with soap, salt, and turpentine, being prescribed together with other treatment.

For some two weeks nothing was found in the stools except ordinary mucus; then on one occasion membranous shreds were discovered after an enema, but were not saved; some days later, a mucous cast, fully eighteen inches in length and about three-eighths of an inch in diameter, was passed; the patient being under the impression that it was a worm, which, indeed, to the untrained eye it resembled. It was composed of semi-translucent, whitish, gelatinous material, manipulable with difficulty, showing no structure under the microscope, except that it contained a few small round cells, lymphoid in appearance; it dissolved readily in alkalies. I regret that its coagulability with acid was not tested.

About a week or ten days later the membrane exhibited was passed. Similar discharges, gradually lessening in quantity and frequency, continued to be observed at intervals for about three weeks. There has been none discovered for more than five weeks past.

Unlike all other cases that I have observed, in this instance these matters were found in ordinary, well-formed stools, that were passed without straining and spontaneously; the discharges were not preceded by colicky attacks or pain of any kind; for the patient's general condition is steadily improving under treatment, so that he is not constipated, is much less hypochondriacal, not at all neurasthenic, eats well, sleeps well, attends to his office and court practice, and has had but two vertiginous spells since coming under my observation.

In this case I think we have a much earlier stage of the affection than any that I have previously encountered, or of which I have read the report. The diagnosis made as to the patient's general condition is lithemia, vasomotor ataxia, gastro-intestinal catarrh, with marked intestinal indigestion. The membranous enteritis I am inclined to look upon as a sequel to the intestinal catarrh, conditioned by the disturbed state of the trophic and vascular system.

The fact that hysteria or hypochondriasis is almost invariably associated with the condition, lends color to the theory that it is literally a trophopathy of neurotic origin, and its most probable mechanism is disturbed vascularization. Even in the other case I have reported in which inflammation probably exists, the paroxysmal occurrence of the attacks indicates a neurotic element.

Bacteriologic investigation was instituted by Dr. Coplin, but his results were not decisive, probably owing to the contaminated state in which the discharges reached him. I am not inclined, however, to regard the condition as in any particular due to microbes. Ordinary intestinal irritation or catarrhal inflammation is its probable starting-point, a neurotic constitution its determining factor.

The American Electro Therapeutic Association will hold its third annual meeting at Chicago on September 12, 13, and 14, 1893. A cordial invitation to be present is extended to all members of the profession interested in electro-therapeutics.

POISONING FROM THE USE OF ENEMATA OF CARBOLIC ACID FOR THE EXPULSION OF OXYURES VERMICULARES.

BY J. A. HAWKINS, M.D.,
OF PITTSBURG, PA.

A MAN recently came to me complaining of pruritus ani, due to seat-worms (oxyures vermiculares.) As I had treated him for the same condition several months previously, I instructed him to use the injection that I had then recommended—a solution of carbolic acid, twenty grains to a quart of water. He stated that his wife and his ten-year-old child were similarly affected, not having been completely cured by the treatment employed. He was instructed to try a solution of the acid again, using, however, a small teaspoonful to the quart of water instead of the twenty-grain solution, and also to expel it at once from the bowel.

Several hours later, on my return from a professional call, I found the man awaiting my coming. He seemed very much excited and told me that he had left the acid with his wife and had then gone out; on his return he found her sitting on the commode. He spoke to her, and she succeeded in answering in but a very incoherent manner. On inquiring as to what was the matter, she answered that she "did not know." The man then became alarmed and went for me. When I arrived I found the woman sitting in a chair in which she had been placed by a neighbor. She seemed rational, and stated that she remembered nothing from the time that she took the enema until she was placed in the chair. She did not recall her husband speaking to her, or, in fact, that he had been in the house. She had given her ten-year-old daughter an enema, but we found the girl asleep, and on being awakened she stated that she felt all right.

I suspected that the drug had occasioned toxic symptoms, but as the woman was of an hysterical temperament and as the menstrual period was expected in a day or two, I found myself between two fires and concluded to try the injection on myself. At five minutes of twelve o'clock, midnight, I injected into my bowel one quart of water, containing in solution two teaspoonfuls of carbolic acid. I sat down in my chair and watched the clock, intending, if any alarming symptoms should arise, to expel the fluid. I noticed the clock strike twelve, and then my ears began to buzz and I became dizzy. The tinnitus aurium produced by quinine was slight in comparison. This is all I remember until I awoke in bed at three o'clock in the morning, undressed and with my clothing in its accustomed place. My mind was a blank from two minutes past twelve o'clock until three o'clock. My wife stated that I had came upstairs some time in the morning and had tried the door (which she had locked when I was called out), and when she opened it I made some remark in a rambling way; that my conduct seemed strange, and that my eyes had a peculiar look about them; that I retired without saying anything further, and had apparently fallen asleep immediately. My mind now was perfectly clear. I remembered taking the enema and recalled the buzzing, and that is all. I knew not if I had turned out the lights or how or when I retired; so I dressed and went down stairs to investigate. I

found that I had slacked my fires, turned out all the lights, lit my night-lamp in the office, and had apparently gone to the closet, as I remembered how it looked before taking the enema, and it was differently arranged when I now entered. I am positive that I expelled the solution before retiring.

I do not recall, nor can I find, that symptoms of carbolic-acid intoxication like the foregoing have been reported; but as similar manifestations were produced in two different individuals, I cannot explain the phenomena otherwise than that they resulted from the acid. I did not notice any great change in the urine such as is usually mentioned; and as to the odor—well, I can still imagine I smell carbolic acid.

In the case of my patient absorption must have been very rapid, as she states that she evacuated the contents of the bowel at once; but I really doubt this, as in my own case there was no knowledge of time by which one would know how long the fluid was retained. There was not the least sensation of burning or stinging imparted during the injection, but the parts felt sore, or as if there was an external hemorrhoid present, for several days thereafter.

Prof. R. Köhler (Wood, 7th edition, p. 604) mentions the cases of two joiners who had applied externally half an ounce of carbolic acid in solution for scabies, with similar symptoms. One was found dead; his fellow suffered from unconsciousness and drunken delirium, ending in restless sleep.

In my own case, there was the dizziness and the unconsciousness, and, in addition, very pronounced tinnitus aurium and apparently sound sleep, as I felt as though I had slept all night when I awoke at 3 A.M.

This experience has taught me that carbolic acid is a more dangerous drug than is by some supposed, and that it should be used with great circumspection if a large surface is to be exposed to it, as in case of pruritus, etc.

From the rapidity of absorption in these cases, it can readily be seen to what purpose the bowel may be used for the administration of nourishment and medication.

810 PENN AVENUE.

THE TREATMENT OF CARBUNCLE.

BY W. M. CAPP, M.D.,
OF PHILADELPHIA.

IN treating a case of carbuncle recently, excellent results were obtained by a strict observance of antiseptic principles. The patient was well advanced in years, of spare habit, nervous temperament, and subject to attacks of acute dyspepsia. He was engrossed in pressing affairs of business, which kept his life more or less on a continuous strain. The condition was aggravated by the oppressive and moist heat of summer weather. When first seen, there was an area of induration and inflammation, fully half as large as the palm of a man's hand, upon the back of the neck, deeply seated, to the left of the vertebral column. At the center of the swelling was one small opening, with a discharge of pus at about a point where the edge of the collar might have set up an irritation. There was no complaint about the general health, but inquiries developed a recent history of a somewhat diminished flow of urine, of a specific gravity rather higher than normal. This was very soon corrected by a few doses of ammonium acetate, with which was combined for general tonic effect some tincture of ferric chlorid. During the whole treatment a simple tonic pill was given after each meal, not so much because of existing indications, as to fortify digestion, and with a view to forestall any depressing effects of the disease. Suitable diet was also directed. Beyond this, no internal treatment was used. Locally, great care was taken to keep the sore and its whole neighborhood clean, in a surgical sense, by antiseptic aqueous solutions, by preference, as neater and more agreeable than greasy applications and as equally effective. The whole area was copiously bathed with a strong solution of boric acid in distilled water, to which was added a little sodium borate and about 20 per cent. of alcohol. By means of a pipette the openings of the sore were gently explored and thoroughly douched with a 1 : 500 mercuric chlorid solution, and finally the whole was covered by a pad of lint saturated with the boric-acid solution, kept moist and in place by an impervious cover and bandage. The bathing, douche, and dressing were repeated three times daily, and in twelve days suppuration had about ceased. Granulating surfaces appeared, the surrounding induration had greatly diminished, and the active inflammation having ceased, the appearances of a healing sore were presented. During the progress of the treatment there was much discharge from nine openings, all of which freely admitted the mercurial douche.

The antiseptic solutions so intimately applied to the suppurating surfaces, and the frequent dressings, doubtless greatly lessened the pain, kept down the inflammation, and curtailed the suppurative process. The frequent evacuation of pus prevented the formation of a "core" and diminished the chances of blood-poisoning from absorption. Also, by this means pressure was removed from the surrounding capillary circulation, which tended to preserve and restore to health much of the adjacent tumefied tissues. Certainly the course of so angry a sore and the time to recovery was brief, and it seems fair to give the credit to the agents used and the mode of their application.

The cure was complete and there has been no indications of a recurrence of the trouble, and the health of the patient has been good during the six months that have elapsed since the treatment.

In a general way, poultices in the treatment of furuncle and carbuncle, as increasing the inflammatory process, are to be objected to. They should be used only when special indications call for them. The same remark applies to the use of the knife, because the system would be doubly taxed in its efforts to heal both the sore and the knife-wound.

2211 SPRUCE STREET.

A CASE OF "ACCIDENTAL" HEMORRHAGE, WITH UTERINE INERTIA.

BY F. W. LOWRY, M.D.,
OF IRON MOUNTAIN, MO.

IN the early morning of June 11, 1891, I was called to see Mrs. O., twenty-eight years old, at term in her fourth pregnancy. In the latter part of the night she had had pains characteristic of beginning labor, which became

suddenly more intense about 4 A.M., when a flow of blood was noticed. When I arrived, the hemorrhage, which was slight, had ceased, and the patient complained only of slight pain in the back.

Vaginal examination discovered the cervix low in the vagina; the os dilated to about the size of a silver quarter; the cervix flaccid; the membranes intact; the head presenting. On abdominal palpation the uterus was found lax.

After an hour, there being no increase of pain and no further show of blood, I left; but called twice during the morning—the last time just before noon, when the pain had ceased entirely. Examination revealed no change since my first visit.

I did not hear from the case again till the evening of June 15th, when I was sent for in great haste, and informed that the patient was flooding badly. I found her with pallid countenance, cold extremities; moist, clammy skin; sighing respiration, weak and rapid pulse. The clothing and bedding were saturated with blood, which was dripping on the floor beneath. There was still a slight flow of blood from the vaginal outlet. Examination revealed about the same condition as was present in the first instance. The head occupied the right oblique diameter. Two fingers could be passed their full length through the os and swept entirely around without reaching the placenta. There was not, nor had there been, any pain.

The question of treatment now presented itself. Immediate delivery was imperative. I believed the uterine inertia, so marked in this case, to be due, partly at least, to over-distention; and later developments proved this to be true.

First ascertaining that the bladder and rectum were empty, and being satisfied that the os would not impede delivery, I gave a dram of fluid extract of ergot in hot water, to insure contraction after the escape of the liquor amnii, and to secure permanent contraction after emptying the uterus, intending to rupture the membranes and deliver immediately with forceps. In ten or twelve minutes the effect of the ergot became manifest in vigorous uterine contractions, a widening os, and tense membranes. I now ruptured the membranes, when it became apparent that the use of the forceps was precluded, spontaneous delivery occurring in a few minutes. The child, a ten-and-a-half-pound boy, was very slightly asphyxiated. The placenta was delivered immediately by expression, a little less than an hour after my arrival at the house. It was very large and extremely friable. The uterus contracted firmly—the tonic contraction of ergot. The mother's pulse now was nearly normal in rate and tension. Before leaving, I repeated the dose of ergot as a safeguard against relaxation. The patient's lying-in was altogether normal. She informed me that between the 11th and 15th she attended to light household duties as usual; that on the evening of the 15th, she was sitting in her room sewing and talking with some friends who had called, when, without warning, the hemorrhage occurred. She lost consciousness, was removed to her bed, and restoratives were applied.

In the latter months of pregnancy there was considerable daily loss of blood per rectum, which ceased a few days before labor and did not return afterward. It did not cause any perceptible impairment of health. It may have served the useful purpose of relieving tension in the friable utero-placental vessels.

This case is reported solely because it presents some unusual features. While ergot accomplished the delivery, it was not administered for that purpose. In spite of the fact that this case seemed specially adapted for the peculiar action of ergot and of the remarkably rapid expulsion of the child, there was some asphyxia, due, I am convinced, to continuous pressure upon the cord and placenta after the membranes were ruptured. Nevertheless, I believe that in selected cases of uterine inertia ergot is indicated—provided the hand that administers the ergot can also, if necessary, reinforce or modify its action with the forceps. The ability to select the cases would presuppose the latter qualification.

MEDICAL PROGRESS.

Cystic Tumor of the Brain Successfully Operated Upon.—At a recent meeting of the New York Neurological Society, Dr. LEO STIEGLITZ reported the case of a woman, twenty-five years old, without hereditary taint and history of previous traumatism or convulsions, who, while quietly talking to her husband, suddenly felt twitchings in the thumb and forefinger of her right hand; the convulsive twitchings spread rapidly, extending to the shoulder and face, and led finally, within the course of a few minutes, to a general seizure, with loss of consciousness, cyanosis, frothing at the mouth, and tonic and clonic convulsions. A similar attack occurred seven weeks later, followed by a number of others. A localized cerebral lesion was suspected, although there was no headache, nausea, giddiness, choked disc. The bromides were given, and after a time there were no general convulsions, but simply convulsive twitchings confined to the right hand and forearm, and always beginning in the thumb and forefinger. These attacks occurred almost daily. Although no history of syphilis could be obtained, specific treatment was instituted, but no improvement followed. In the course of time, a marked paresis of the right hand developed. The deep reflexes were exaggerated, the more decidedly on the right. The urine contained neither albumin nor sugar. There was no elevation of temperature. Sensation was preserved, except for a feeling of numbness in the right hand and arm. A diagnosis of organic lesion, probably a tumor, situated in the left anterior cerebral convolution, was arrived at. An operation was decided upon. A lateral opening in the skull having been made, the dura was seen to bulge but slightly into it. An area on the dura about the size of half a dollar, presented a diffuse yellowish tinge, different from the color of the adjacent dura. The application of the poles of a small faradic battery to the unopened dura, promptly located the center for the movements of the hand and fingers, and the point corresponded with the discolored area referred to. When the dura was opened, the cortex of the brain showed no apparent change. A vertical incision into its substance was followed by a gush of yellow serous fluid, none of which, unfortunately, was saved. Perhaps one ounce of fluid escaped. The walls of the cyst were found to be perfectly smooth. A small layer of gray matter was removed from the center ex-

posed, to prevent disturbances that might develop from possible secondary sclerotic changes. There was but little shock after the operation. On the following day the patient had no power in her right thumb and forefinger, and could move her other fingers and the entire right arm but very slightly. These symptoms gradually improved. Four weeks later the patient had slight convulsive twitchings in her right hand, arm, and face; after the lapse of another week she had more violent twitchings. Ten days later the scalp wound was opened, and the flap of skin was found adherent to the dura. Probing failed to reveal a reaccumulation of fluid in the cyst. The adhesions were separated, and a flexible gold plate was inserted. Two days afterward slight twitching occurred in the three ulnar fingers; the patient could move her fingers, hand, and arm quite extensively. Upon examination, three months later, it was found that the patient had lost the sensation of position in the fourth and fifth fingers of the right hand; she could not tell whether they were flexed or extended. The strength of her hand and arm was greatly increased. In the following month there was considerable twitching in the right arm and face. The patient had been kept on from fifteen to thirty grains of potassium bromid per day following the operation. The conclusion is expressed that the condition is dependent upon the presence of a glioma.

A New Theory of Sleep.—ROSENBAUM (Thesis, Berlin, 1892; *Centralbl. f. klin. Medicin*, 1892, No. 49, p. 1054) defines sleep as that condition of consciousness in which the psychic and physical forces are reduced, in greater or less degree, in accordance with the individuality, below the level normal to waking, or under circumstances are entirely suspended. This reduction of force follows as the result of preceding fatigue of the nervous system induced by the activity of the waking hours. The real essence of fatigue resides in a swelling of the nerve-cells, in the presence of an increased quantity of water in the nerve-substance. This absorption of water stands in inverse proportion to the nervous activity; the greater the quantity of water the slighter the irritability, which may disappear entirely. The absorption of water occurs in consequence of the chemical decomposition of the nervous tissues that takes place as a result of the activity. The water thus produced is expired by the lungs as vapor, a small portion in the course of the day, the larger portion, however, during the night, in the course of sleep. The absorption of water from the various organs into the venous circulation is governed by the laws of hydro-diffusion, and is dependent upon the volume and density of the blood, upon the presence of solid constituents, the velocity of the blood-stream, etc. The dissipation of water into the air is governed by the laws of gaseous diffusion, and is dependent upon the air-pressure and the matters contained in the water. On account of the disproportion between the absorption of water and nervous activity, those centers that have furnished the smaller proportion of work will be aroused the earlier—there thus result partial sleep and partial waking at the same time. The ideas cannot be associated—and dreaming is the result. If, on the one hand, a portion of the centers and motor nerves are so far aroused as to send out impulses and convert these into mechanical work, while, upon the other hand, the remaining centers are still so profoundly wrapt in sleep as not to be aroused by these stimuli, the condition of somnambulism results. The nutritive elements assimilated and stored up in the organism take the place of the water thrown off during sleep. The recuperation of the physical and psychic forces after sleep results from this interchange. Intelligence stands in inverse ratio to the percentage proportion of water in the brain, and is to be measured by this standard—at least in the child.

A Fatal Case of Acute Ascending Paralysis.—WATSON (*British Med. Journal*, No. 1667, p. 1286) has reported the case of a coal-miner who, after partaking of beer to the point of intoxication, lay on the damp ground and went to sleep for four or five hours. He was then carried home and put to bed. On the following morning, on attempting to rise, he found that he could lift his legs only with great difficulty, and that the thighs were weak; there was also an aching in the lower part of the back, with much formication in the feet and hands. The symptoms grew progressively more aggravated, and after five days there was complete paraplegia. There was no anesthesia, no ankle-clonus; and the knee-jerks were absent on both sides. The pupils reacted sluggishly to light and in accommodation. Heart, lungs, and urine presented no abnormality. A day later, the lower extremities were entirely paralyzed, and the abdominal muscles were becoming affected. There was, however, no incontinence of urine or of fecal matter. During the day the paralysis rapidly extended upward, involving successively the abdominal, the lower and the upper intercostal muscles; next those of the hands, arms, and shoulders, and, finally, the diaphragm, swallowing becoming impossible, and suffocation ending life. Toward the last, speech became affected, and the masticatory and facial muscles became markedly weakened, so that the eyelids could not be firmly closed or the mouth pursed up, as in whistling or blowing. In treatment counter-irritation was applied to the spine and ergot was administered internally. At the post-mortem examination the viscera were found healthy. The membranes of the cord were congested. The cord itself presented no lesion, macroscopically or microscopically.

The Etiology of Essential Anemia.—KRÜGER (*St. Petersburger medicin. Wochenschr.*, 1892, No. 50, p. 471) expresses the opinion that anemia is never a disease *sui generis*, but is in every instance only a symptom. In a study of the comparative determinations of the residuum and of the hemoglobin in the blood of the afferent and efferent vessels of the spleen he found that the blood of the splenic vein was richer in dry residue and hemoglobin than the blood of the splenic artery. The increase or diminution in blood coloring-matter corresponded with the increase or the diminution of the dry residue. The conclusion is arrived at that hemoglobin, in addition to being broken up, is also manufactured in the spleen, construction, as a rule, exceeding destruction. Finally, the view is expressed that pernicious anemia and chlorosis, both of which are considered as the expression of a common condition of varying intensity, are dependent upon irritation of the sympathetic nervous system, resulting in altered function of the spleen.

Spontaneous Closure of Rupture of the Uterus —RICHTER (*Deutsche med. Wochenschr.*, 1892, No. 45, p. 1012) has reported the case of a woman in labor to whom he was called by a midwife, because, at the time when it was expected that the head was about to be expelled, the parturient suddenly vomited and lost consciousness and the pains ceased. Rupture of the uterus was at once suspected and steps were taken to turn and extract the child. The child was delivered in a state of asphyxia and could not be resuscitated. It became necessary to remove the placenta manually. This was found free in the uterine cavity, while a defect was noted on the left side of the anterior wall of the uterus. A two-pound sandbag was placed upon the abdomen, fifteen minims of ergot were given every hour for three hours, and fifteen drops of tincture of opium were administered three times daily. There was inconsiderable hemorrhage and the woman slowly recovered.

Prurigo.—At the Second Congress for Dermatology, recently held at Vienna, VIDAL (*Monatshefte f. prakt. Dermatologie*, xvi, 1, p. 11) expressed the view that prurigo, like lichen simplex circumscriptus, is a chronic papular neuro-dermatitis, anatomically belonging in the category of papular affections, but pathogenetically being a dermato-neurosis. The affection is not an independent disease, but results from a number of pathologic conditions, of which the two most important are a neurotic disposition and a lymphatic constitution (the scrofulous diathesis of older authors.) The affection usually makes its appearance in the first two years of life, though its manifestations may be first observed during a later period of childhood, or still later. Although recovery is not the rule, it is not of rare occurrence. Well-directed management may be followed by improvement and remissions of long duration, particularly if the skin be protected from irritation of all kinds.

Incoercible Vomiting and Salivation of Pregnancy, Requiring Abortion.—DAVIS (*Chicago Clinical Review*, i, 3, p. 221) has reported the case of a deutipara, thirty-seven years old, in which, in the third week of pregnancy, vomiting and salivation set in. For more than a month the usual remedies were employed, but without success, the phenomena persisting, and the woman steadily losing ground. Finally, it was determined to empty the uterus. The os was first dilated by means of tents, and a soft-rubber male catheter was afterward introduced into the uterus. After a little time the embryo was expelled, but it was necessary to remove the secundines instrumentally. No unpleasant sequelæ appeared, and the vomiting and salivation gradually subsided. The woman had suffered similarly from the third week throughout her previous pregnancy, but in less intense degree.

THERAPEUTIC NOTES.

Potassium Bitartrate for the Ascites of Hepatic Origin.—SASAKI (*Berliner klin. Wochenschr.*, 1892, No. 47, p. 1184) has reported eight cases of chronic interstitial hepatitis of portal type, one case of biliary type, and two cases of syphilis of the liver, in all of which the ascites present was greatly relieved by the administration of full doses of potassium bitartrate. If the nutrition be impaired, iron, quinine, cod-liver oil, and good diet may be given conjointly. Not much benefit is to be expected when the ascites is dependent upon malignant disease. The dose varies from two to ten drams in the course of the day; an average quantity would be from two and a half to five drams daily; the best dose is that which will cause two or three bowel-movements. If the accumulation of fluid is very large, paracentesis may be practised in conjunction with the administration of potassium bitartrate. The drug is, as a rule, well borne, and in cases may be given for months. Its good effects are to be ascribed to its laxative and diuretic action.

Arsenic as a Prophylactic.—Governed by a statement that persons taking arsenic are insusceptible to vaccination, BRYAN (*Brit. Med. Journ.*, No. 1665, p. 1187) employed the drug as a prophylactic in scarlet fever, and believes that he has by this means checked an epidemic. In a family in which one child had severe scarlatina, arsenic was given to the other two children, who were not attacked, though they continued to be about the patient until she died, after three weeks. In another family, a boy, seven years old, had scarlet fever, but the four other children, from three to eleven years old, did not contract the disease; while the mother aborted, but was not herself attacked by the disease. There is evidence that arsenic is valuable also as a prophylactic against diphtheria and influenza. Bryan gives gr. $\frac{1}{10}$ of arsenious acid, or ♏ij. of the official solution of potassium arsenite, three times a day for the first week and afterward twice a day.

Ferric Chlorid in the Treatment of Diphtheria.—HUEBNER (*Therapeutische Monatshefte*, vi, 12, p. 640) reports the treatment of fifty-two cases of diphtheria by means of topical applications of the solution of ferric chlorid, with but two deaths; scrupulous attention at the same time being given to the general management of the case.

ROSENTHAL (*Ib.*, p. 641) reports the employment of a 2 per cent. solution of ferric chlorid in water to which a small quantity of glycerin has been added, of which from a teaspoonful to a tablespoonful was given every hour. Seventy-nine cases were thus treated, and of these six terminated fatally.

For Hiccough.—In a case of obstinate hiccough in an elderly man of gouty tendency, SYMES (*Dublin Medical Journal*, December, 1892, p. 488) succeeded in controlling the spasm by the administration, every sixth hour, of the following combination:

℞.—Potassii iodidi	. . .	gr. iij.
Chloral. hydrat.	. . .	gr. v.
Potassii bromidi	. . .	gr. vij.
Potassii bicarbonatis	. .	gr. xv.—M.

Ergot for Atony of the Bladder.—REGINALD HARRISON (*Clinical Journal*, i, 3, p. 95) warmly recommends the employment of ergot in the treatment of atony of the bladder, and also of hematuria associated with prostatic enlargement:

℞.—Ext. ergotæ fluid.	. . .	gtt. x.
Aquæ cinnamomi	. . .	f℥j.—M.

S.—Three times daily.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. SATURDAY, FEBRUARY 11, 1893.

STATE BUREAUS OF LIVE-STOCK INDUSTRIES.

THE scientific investigation in public and private laboratories of the causes of diseases that afflict the human family, especially those of microbic origin, with the object of their prevention and cure, is of immense importance, not only for the prospective value of discoveries that may be made in the line of original research, but also for the benefit to be derived from teaching what has already been discovered. There is a wide range for exploration and research in the domain of the etiology of disease, and there is also room for the dissemination of the results of discoveries that have given to modern investigation so much merited distinction.

A collateral branch of inquiry, likewise most beneficial in its results, is that which embraces the investigation of diseases that affect domestic animals, both those that may be transmitted to man, and those that are peculiar to animals. The economic advantages of such investigations are very great, as it can be shown beyond a doubt that millions of dollars are lost every year in the United States by the ravages of disease among domestic animals, which belong to the preventable class. To save this great loss, as well as to restrict and suppress disease that may be conveyed in various ways from animals to man, is certainly a humanitarian undertaking, and as such deserves encouragement and support. The Bureau of Animal Industry instituted under the general government has this twofold object in view, but the labors of this organization should be supplemented by efficient bureaus under State management, all working in coöperation for the same end. Such an arrangement would secure to the State the manifold advantages of an authoritative organization, charged with the investigation and the supervision of measures for the suppression of diseases communicable from animal to animal, and from animal to man. It could with advantage be attached to the State Agricultural Department, or to the State Board of Health. Its functions should not only be to investigate these diseases and seek to improve the knowledge already procured, but also to disseminate information amongst farmers and stock-raisers, and furnish data upon which the needed legislation could be formulated, as well as to give advice and lend aid in stamping out diseases that occasionally appear amongst herds of cattle.

We have been led to these remarks by the perusal of a bill recently introduced in the Legislature of Nebraska for the establishment of a Bureau of Live-stock Industries, and for the erection and maintenance of a patho-biologic laboratory for the investigation of infectious animal diseases in connection with the work of the said bureau, and for the further protection of the interests of stock-breeders. It is proposed that the officers of the bureau shall consist of a veterinarian and assistant, a chemist, veterinary inspectors, and such other officials as may be found necessary. The director of the patho-biologic laboratory shall be an experienced veterinarian, who must have an acknowledged reputation in the investigation of live-stock diseases. The veterinarian is made responsible for all the work of the bureau, and for the general direction of its officers; he is also to make or direct and supervise continuous and careful study of the diseases of live stock, especially with a view to their prevention, cure, or eradication.

The assistant veterinarian, as chief executive officer of the bureau, is responsible for the faithful and prompt action of the veterinary inspectors, and such other officers as may assist in the work. He is also charged with the duty of supervising the traffic and movement of live stock within the State in its relation to the spread of infectious diseases. The execution of the laws and regulations for the

suppression and prevention of infectious or other diseases in the live stock of the State is placed in the hands of the sheriffs of the counties, the marshals or chiefs of police of cities or towns, or such officers as are charged with the execution of the laws in general. The officials of the bureau are authorized to enter any premises on which infectious disease is known to exist among any species of domestic animals, or is suspected to exist, for the purpose of examining said animals, and of executing the laws of the State. Power is given to condemn and kill any animal or animals in which an infectious disease exists, or is supposed to exist; or to securely quarantine such animals, according to circumstances. Provision is made for indemnification of the owners of animals after appraisement, but only in certain cases.

An important provision of the bill is one that requires the owner or owners of live stock, and any person who may have knowledge of the existence of any infectious disease in any live stock in the State, or who may have knowledge of symptoms that excite a suspicion in his mind that the disease may possibly be infectious, to immediately notify in writing the sheriff of the county, or proper officer, of the existence of such disease, or of the existence of his suspicions.

Selling or disposing of any animal or animals in which an infectious disease exists; or bringing into the State such diseased animals; or allowing the same to be with healthy animals, is made punishable by a heavy fine. Stock-yards must be provided with a competent inspector at the expense of the owners. Railroads are prohibited from transporting diseased animals. Provision is made for disinfecting cars in which such animals may have been transported.

The bill appears to have been drafted by a competent hand. Its provisions are comprehensive, wise, and salutary. The effect of their efficient enforcement would be in time to eradicate from the State those diseases that are so destructive to live stock, and that in some cases are dangerous to the human family, and thereafter to guard against invasions of disease. Leaving out of the question the protection of human life, the immense economic benefits to be reaped from the enforcement of such a law are alone sufficient reason why it should receive legislative sanction.

The sooner people discard the idea that they have a license to do as they please with what they call their own, independently of the influences of their acts upon the community, and learn to yield a hearty coöperation with the beneficent provisions of the law intended for the weal of the entire community, the sooner they will realize the advantages and protection that such laws afford them. It would be well if each State had its Bureau of Animal Industry and hearty coöperation were established among them; for the advantages of concerted action would be prompt and general, and would show in striking contrast with the results of the efforts of the few isolated stations in the country, which are hampered and restricted through the lack of coöperation on the part of other States.

THE INFECTIOUSNESS OF HERPES ZOSTER.

WHILE not a common affection, herpes zoster is not at all a rare affection. Usually an acute disorder of brief duration, tractable and self-limited, it generally falls into the hands of the general practitioner rather than of the dermatologist. The disease is usually supposed to be a tropho-neurosis dependent upon lesions of the nervous system, and most commonly an affection of the peripheral nerves. The condition has been observed in conjunction with traumatism, erysipelas, syphilis, malaria, rheumatism, tuberculosis, and catarrhal affections.

WASILIEW[1] takes issue with the commonly accepted view as to the etiology of herpes zoster, basing his conclusions upon a review of the literature and upon a study of 274 cases gathered in a collective investigation by the Medical Society of Thüringen. He finds many reasons for excluding the nervous influence and for accepting an infectious origin. He points out that the phenomena presented by the disease clinically correspond closely with those observed in other infectious diseases. There is usually a prodromal stage, which may be marked by malaise, nausea, headache, gastric derangement, and local itching or burning. Fever is not uncommonly present, sometimes before the appearance of the eruption; at other times after the eruption has appeared. It may last two or three days, to disappear with the eruption, or it may persist after this has disappeared. In a small number of cases involvement of the nearest lymphatic glands has been observed. At the site of the eruption there is usu-

1 Herpes Zoster und dessen Einreihung unter die Infectionskrankheiten. Besonderer Abdruck aus der Correspondenz-blätter des allgemeinen ärztlichen Vereins für Thüringen, Jahrgang xxi, No. 5. Jena: Gustav Fischer, 1892.

ally burning, itching, or pricking, and commonly there is intense neuralgic pain. There are on record not a few instances of epidemics of herpes zoster, and evidence is not wanting as to direct infection. One attack usually confers immunity to subsequent attacks, though, as in other infectious diseases, recurrence sometimes takes place. Finally, protozoa have been found in the diseased skin.

In antagonism to the view of the nervous origin of the disease, it is pointed out that the affection does not always pursue the course of a single nerve, as has been stated; neither is it always confined to one side of the body. Its distribution is better explained by the blood-stream. In some cases lesions of the nerves have been found; the vessels have, however, usually suffered as well. In a few cases no changes whatever have been demonstrable. It is not at all unlikely that under the conditions first noted the changes in the several tissues have been due to a common cause.

The views outlined in the foregoing can thus far be considered only as hypothetic, and in support of which further evidence must be presented. The theory is on its face a plausible one. Careful observation, however, with the new light shed upon the subject, will be required for its substantiation before it can receive general acceptance. One cannot be too guarded at this day, when the tendency is so universal to ascribe all affections to a definite specific infection.

EDITORIAL COMMENTS.

The Parasitism of Disease.—The list of diseases of demonstrable parasitic origin is constantly growing. An analysis of the successive stages through which our views upon the infectious diseases have passed makes an interesting study. For a while investigators were bent upon finding a specific microorganism for every well-defined disease. It took some time to learn that while the microbe is the most important factor in the development of the given disease, it is not the sole element. Then began the study of the products of the bacteria, which was soon followed by remarkable developments in the direction of immunity and cure. For a time the vegetable organisms occupied almost universal attention. Now the scene has changed. With Laveran's description of the hematozoön of malarial fever a new line of investigation was opened, in which but little progress was made until recently. Great interest attaches to the study of the animal parasites of certain infective diseases. We know that a form of dysentery is dependent upon a protozoan ameba. Testimony is accumulating in favor of the etiologic dependence of carcinoma upon animal organisms. More recently still an observer describes characteristic animal organisms associated with measles, scarlatina, syphilis, and smallpox. We conclude as we began: The list of infectious (parasitic) diseases is constantly growing.

The Official Languages at the Pan-American Medical Congress.—*The Deutsche medicinische Wochenschrift*, of January 12, 1893, p. 47, contains an open letter from the distinguished German surgeon CZERNY (who is an honorary member of the American Surgical Association), addressed to our own MASTIN, politely declining an invitation to attend and participate in the sessions of the Pan-American Medical Congress, because, as he quotes, "the languages of the Congress shall be Spanish, French, Portuguese and English," "although remarks in any other language will be permitted, provided one of the members present expresses a willingness to make a translation into one of the four official languages." We presume that German was not included in the list as not being one of the languages of any of the countries of America, but, as CZERNY points out, the important place that German literature holds in the scientific world; the large number of Americans that complete and elaborate their medical education in Germany, and the frequency with which the German language is used in parts of America, would seem to make it not only desirable, but also imperative, that addresses at the Congress be permitted to be made also in German, unless it is intended that the proceedings be conducted only in the languages of America.

The Function of the Thyroid Gland and the Therapy of Thyroid Disease.—The function of the thyroid gland is an undeveloped chapter in human physiology. That this organ subserves quite an important part in the animal economy would seem demonstrated by recent experimental and surgical experience. Whether the influence be a nutritive or a chemical one, it is clear that the nervous system bears the brunt of thyroid disease. It is reasonable to assume that the thyroid, directly or indirectly, neutralizes certain products of normal metabolism, which, unacted on (in consequence of the removal of the functional influence of the gland), by their presence give rise to the phenomena that we recognize clinically as exophthalmic goiter, myxedema, cretinism, and the cachexia strumipriva, as well as other conditions, without a definite place in our nosology. The recognition of this fact has led to the therapeutic employment of the thyroid gland or of an extract prepared from the gland, by subcutaneous injection, by grafting or by the mouth;

and to the precaution of not removing operatively the entire gland; the results of which in turn support the view of the function of the gland suggested.

An Illustration of the Fallacies of Statistics.—It is an old saw that statistics can be made to prove anything. That they must be used with intelligence, and not mechanically, is well known. This fact cannot be better illustrated than by the statement of an able ophthalmologist of England, who, in a recent issue of the *Lancet*, reports in 10,000 cases of eye disease 4441 cases of emmetropia. American oculists at once recognize that their European brethren understand the term emmetropia very differently from themselves, and that they also differ very greatly as to the proper methods of its determination. It is an important omission on Mr. Carter's part that he does not define his terms. Some of our best ophthalmic surgeons doubt if they have ever seen a case of emmetropia, and at best the proportion is exceedingly small. In the same way that in 10,000 cases, 3148 should be myopic and only 2323 hyperopic, is widely at variance with American case-record book.

Tammany vs. The People of the United States.—With absolute unanimity the New York Academy of Medicine has condemned the New York quarantine system and management, and has appointed a committee to go to Washington and protest against the mutilated and crippled Quarantine Bill now pending before the Senate. A similar action had previously been taken by the College of Physicians of Philadelphia. The voice of the entire medical profession should be heard no less plainly and indignantly against the degradation and shame of endangering the lives of the whole people for the financial benefit of a crowd of politicians. It is now simply a question of choice between the national health and safety and the continuance in office and plundering of a few incompetent ward-politicians. If every medical society would also act as it should there would soon be an end to this brutal and outrageous selfishness.

A National Health-Organization.—However important the nationalization and stringent systematization of quarantine may be (and no public health measure is more so), it yet remains equally true that to prevent and stamp out disease within the lines is quite as necessary, and in the long run, is even more important. There are to-day, for example, thousands of unacclimated immigrants in the Southern States, and with warmer weather an epidemic of yellow fever, always more or less endemic there, may burst forth with malignant energy. Simple common sense and self-preservation must bring about a national health-organization, whose office it shall be to deal with all questions appertaining to the prevention of disease, if possible, and failing in this, putting to use a machinery capable of coping with widespread epidemics of any and all kinds when they arise. Why must we wait till taught by the bitter lessons of experience and death?

An Epileptic Colony in New York.—A committee of the State Board of Charities has recommended to the Legislature the purchase of a farm in Livingston County, to be used as a colony for the 500 or more epileptics now scattered about among the poorhouses. A similar movement is afoot in England. For the sake of the patient, the State, and civilization, it is most urgent that the legislation authorizing the movement may be speedily enacted, and that other States and all States may adopt this wise and humane method of procedure.

The Lancet Relief Fund.—Every year, in the month of January, the proprietors of the London *Lancet* provide a sum of money of not less than $1500, for the purpose of affording immediate pecuniary assistance to medical men, or their widows and orphans, in cases of distress and emergency, by the grant of money, by way of loans, free of interest, or gifts, as the circumstances may require.

Typhus Fever in New York.—The attention directed to cholera renders the people and the medical profession indifferent to the fatality and danger of other diseases. It is quite true that our country is almost, or quite as much, in danger from typhus as from cholera. There have lately been somewhat more than over 200 cases in New York City. It seems impossible to prevent their continued reappearance, and the disease may soon spread to other cities and States.

CORRESPONDENCE.

THE NEED OF SPECIAL HOSPITALS FOR THE TREATMENT OF TUBERCULOUS PATIENTS.

To the Editor of THE MEDICAL NEWS,

SIR: The onward march of that dread disease, tuberculosis, is not to be wondered at, if we consider the little that is done to prevent or arrest it. Little or no provision has been made in the hospitals for the care and treatment of tuberculous patients. On the contrary, they are received as an unavoidable burden, and are crowded into wards, where they are more or less smothered in their own exhalations and excretions, on the supposition that they will die anyway. In bad weather all are confined to the wards twenty-four hours in the day, and those bedridden necessarily all of the time, and often in wards of which the ventilation is remarkable for its absence or its total inconsistency with ordinary hygienic laws. Moreover, absolute cleanliness is not attainable in wards

or rooms occupied throughout the day and night; but without these, such a place serves as a nidus and an incubator for the propagation and maintenance of disease.

When a physician is consulted by a person of means who has, or fears that he has, pulmonary tuberculosis, what is the usual advice given? After a careful physical exploration and a "sizing up" of the patient generally, in regard to idiosyncrasies, etc., the advice given is change of climate, and a place is usually designated where the pursuit of health and happiness may possibly be succcssful. This prescription given to a person of means can easily be followed, and usually with beneficial results; but in the case of the poor it is quite a different matter. People of moderate means, who are tied down by business cares, and the poor, are thus deprived of the "treatment" which at present is the only one that can be said to exert any distinct influence upon the disease. It is for this class that I wish to enter a plea and to suggest methods by which they may be benefited.

A hospital designed to meet the needs of this class of patients must be especially constructed for that purpose, and should contain day and night wards, so arranged that beds, etc., can readily be transferred from one to the other. The wards should be of medium size, with facilities for admitting floods of light and sunshine. Furthermore, they should be *air-tight*, ventilation being provided for as I shall hereafter describe. This is readily accomplished by laying the floor of tiling in good cement, and covering the walls and ceiling with a good quality of cement. The windows should consist of large plates set in lead frames and cemented in place, and the doors should be provided with rubber packings. The walls and ceilings should be painted with good paint and then varnished. The tiled floor should be laid so as to be higher near the walls and sloping slightly toward the center of the room. A room thus prepared can be rendered absolutely clean and aseptic by flooding it daily with a spray or stream of mercuric chlorid, the walls, ceilings, and floor being then scraped with rubber scrapers and dried with mops. The mercurial solution runs into a tank beneath the floor, where it is allowed to collect, and can be used many times, as its antiseptic qualities, of course, are not diminished.

The ever-increasing cheapness and utility of electricity recommend it as an agent to be used indirectly as well as directly in the treatment of disease, and in the present instance this agency would play an important part in the system of ventilation I am about to describe. We will trace the air from its ingress to its egress. As it is drawn in, the air is forced through a solution to free it of carbon dioxid. It is then rendered warm and aseptic by passing slowly over and among coils of wire rendered incandescent by electricity. It could then be treated as experience would best indicate; that is, it could be rendered dry or moist, charged with additional oxygen or other medication; by passing it through a drying mixture or a spray, medicated or otherwise. A supply motor and fan then forces the air into the ward through numerous openings near the ceilings and from all sides. The air escapes from similar openings near the floor, being drawn out by another motor and fan and is discharged into some antiseptic mixture and allowed to escape. A gentle current is thus maintained in the room from above downward, which would not allow the bacilli-laden dust to rise high enough to be inhaled.

The object of having two motors and fans is to regulate the *pressure* in the ward so as to simulate at will the mountain air, the pressure at sea-level, or in the valley below sea-level. The room being air-tight, any degree of pressure from the lowest to that of two atmospheres can be obtained. The pressure can be regulated automatically by a barometer with electric connections, which can be set at any level. If the pressure becomes too great the barometer, of course, rises, makes the connection to increase the speed of the egress motor, thus drawing out the air more rapidly than it is forced in, and *vice versa*. An electric thermometer controls the temperature automatically in the same way and keeps the wires more or less incandescent, according as the temperature is increased or lowered. The lighting should be by electricity, to avoid the products of the combustion of oils, etc. So much for the mechanical part of the subject. The furnishings should consist of as little as possible and should be of iron, which an occasional mercurial bath would not damage. The bedding should be completely changed daily, washed and wrung out of a 1:1000 mercurial solution, and allowed to dry. The foregoing system, combined with the ordinary therapeutic measures, I am convinced would be the means of saving many lives and relieving much suffering.

This is merely an outline of a system that I would like to see inaugurated in the United States, where the wealth and generosity of its citizens enable such a project to be not only possible but probable, especially when fostered and aided by skilful physicians.

Respectfully, A. T. WEBB, M.D.

87 VIA NAZIONALE, ROME, January 9, 1893.

A "CANCER CURE."

To the Editor of THE MEDICAL NEWS,

SIR: Wood-sorrel (oxalis acetosella), written of in your journal for January 28 (p. 110), is not a new remedy for carcinoma and it has better support than the testimony of old women. It has received professional indorsement, and professional evidence has been presented in its favor. A search through my reference books has been in vain, however, and I call attention to it because others may be more fortunate. My impression is that I saw notices of it in the *Brooklyn Med. Journ.* or *Annals* many years ago. Respectfully, J. C. REEVE.

DAYTON, OHIO.

THE KEELEY SYSTEM.

To the Editor of THE MEDICAL NEWS,

SIR: I was very much interested in an article on alcoholism, by H. Ernest Schmid, published in THE NEWS of January 28. The author seems to have hit upon the essential plan of the Keeley system, that of "operating on the mind and of restoring the dethroned will-power."

As we are located near Dwight, many patients from this city have been there, and from various conversations with them, and after hearing a description of their symptoms while taking the treatment, I have come to the conclusion that the following, obtained from one of

the graduates who had the medicine analyzed, is the secret of the Keeley cure.

Patients on entering the institute are given a mixture containing

℞.—Aurii et sodii chloridi . . .	℥ss
Strychninæ nitrat.	gr. iv.
Atropinæ sulph.	gr. j.
Glycerini	℥ij.
Ex. fl. cinchonæ q. s. . . .	℥xvj—M.

Sig.—One teaspoonful in water three times a day.

The members report four times a day and receive a hypodermatic injection of strychnine nitrate gr. $\frac{1}{60}$. They are told that they can have all the liquor they want. "If you feel like taking a drink," says the doctor, "just ask for it." Mark you now, here is the secret. If the patient asks for a drink of whiskey he gets it; but instead of the injection of strychnine nitrate, he receives one of apomorphine, gr. $\frac{1}{10}$. Of course, the whiskey makes him sick; he is unable to retain his once favorite beverage, and he promptly informs his fellow undergraduates, and writes his friends glowing accounts of the great change and new life that have come over him since taking this wonderful cure, which he feels sure could only have been brought about, as Mr. Keeley himself said in a lecture here recently, by divine appointment.

The reason why Mr. Keeley does not give his secret to the profession is obvious. Respectfully,

J. J. BROWNSON, M.D.

DUBUQUE, IOWA.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXII. SATURDAY, FEBRUARY 18, 1893. No. 7.

ORIGINAL ARTICLES.

A RÉSUMÉ OF SOME MODERN METHODS OF THE DIAGNOSIS OF DISEASES OF THE STOMACH.

BY D. D. STEWART, M.D.,
CLINICAL LECTURER ON MEDICINE IN JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

THERE is in medicine no subject the study of which can be approached with a livelier degree of interest and satisfaction by the clinician than that of diseases of the stomach. Under modern methods of research, these ailments offer an extended range for profitable inquiry, and a scope, the result of exploration, which is not alone of interest to the investigator, as is unfortunately often the case with the familiar organic affections of certain other organs —such, for example, as those of the nervous system. These, though of absorbing satisfaction to follow through their intricacies of diagnosis, are—and probably ever will be—almost a barren field to the therapeutist. The end for which we gain our knowledge—the cure of disease—is in affections of the stomach less hampered by "the old and inevitable antagonism between pathology and therapeutics"[1] than in ailments of any other viscus.

Recent diagnostic methods, aided by the teaching of the laboratory, not only often enable us to arrive at the nature of the disorder with an astonishing degree of exactness, and to formulate a therapy most successful in result, but they also render it as unnecessary as it is impossible to wait for post-mortem revelations as to the nature of the pathologic process. In diseases of the stomach, in which the workings of a disordered viscus can be studied and compared with the normal, we are enabled to learn so much regarding the pathology of curable diseases, that the reproach, often just, that modern scientific medicine has the tendency to create a greater interest in the study of a disorder than is taken in the patient's well-being, cannot hold here.

The diagnostic methods of inspection, palpation, and percussion, applied to the study of stomach diseases, need not be here detailed, their general application being understood. Regarding palpation, two points, upon which especial stress should be laid, may be noted in passing: (1) that it should always be performed with the hand placed horizontally upon the abdominal wall, and never with it held perpendicularly or obliquely; and (2) that when palpation in dorsal recumbency is resultless, an examination in the knee-elbow and lateral position should not be omitted. It is often necessary that these external methods of examination should be conducted under artificial distention of the stomach, either alone or, conjointly, of the large bowel, with gas or water—or, when the combined method is used, one viscus may be distended with gas, the other with water.

The stomach, more especially its inferior margin, may be outlined when empty and the patient erect, by first noting the lower line of tympanitic note its percussion evokes, if it be possible to thus differentiate transverse colon and stomach. A pint or more of water is now introduced, and if necessary the colon distended with air by a hand-ball syringe, or by the inverted siphon of a bottle of carbonated water. The method of Dehio, a modification of this, is of still greater utility. About a quart of water is introduced in separate quantities of a half-pint each, and after the ingestion of each portion, the lower crescentic limit of flatness against the tympanitic transverse colon is outlined. In the erect posture, though the normal stomach descends somewhat with the increased amount of fluid introduced, it will not quite reach the level of the umbilicus. In cases of relaxed muscularis the descent is more rapid, and in pronounced ectasia and in gastroptosis the stomach is already abnormally low before the introduction of fluid. Another method employed is, with the patient recumbent, to distend the colon with water and the empty stomach with gas, either by generating it *in situ* by the administration separately of the acid and alkaline portions of one or two Seidlitz powders[1] in concentrated solution, or by the introduction of air through a stomach-tube by an ordinary enema-syringe. The former is a more rapid method of obtaining distention, but often not quite so satisfactory in result when applied in cases of decided gastrectasia.

Among the newer methods of exploration must be mentioned gastrodiaphany of Einhorn.[2] With this, valuable aid may be obtained in outlining the

[1] Gowers: Syphilis and the Nervous System.

[1] A teaspoonful or two of sodium bicarbonate and about two-thirds this quantity of tartaric acid may be used to replace the Seidlitz powder.

[2] See the New Yorker med. Monatsch., November, 1889; the New York Med. Journ., December 3, 1892.

size, situation of the stomach, and, in certain cases, the condition of the anterior gastric wall. Einhorn's gastrodiaphane, made by Reynder & Co., of New York, consists of a soft stomach-tube, at the gastric extremity of which is placed an Edison's hard-glass lamp, from which conducting wires, containing a current-interrupter, run to a portable storage-battery. This apparatus, which is really very practicable, is as easy of introduction and manipulation as the ordinary stomach-tube. In its application the stomach should be free from food and moderately distended with water.[1] When considerable faucial irritability exists a cocaine solution should be first applied to the throat.[2] The stomach extremity of the gastrodiaphane, after being lubricated with oil or glycerin, is guided over and past the epiglottis by the index-finger of the left hand, much as a hard tube is introduced. After its passage, the circuit is closed. If no pronounced thickening of the anterior stomach-wall exists, trans-illumination in a dark room, with the patient erect, permits the outlines of the stomach to be seen as a zone of reddish hue on the abdominal wall.

The actual utility of gastrodiaphany over other methods of outlining the stomach lies especially in the application of the diaphanoscope to the differentiation of gastroptosis from gastrectasia, as by it the determination of the site of the lesser curvature is far more readily made than by inflation. It also is of real value in diagnosticating tumors or thickening of the anterior wall of the stomach, the presence of these interfering with trans-illumination.[3]

The most notable of the advances made in the diagnosis and treatment of diseases of the stomach dates from the application of the stomach-tube to diagnostic purposes by Leube, in 1871, and the subsequent introduction of the soft tube by Ewald, for similar uses. An insight was thus obtained better than ever before as to the gastric chemism, and extraordinary opportunity given not only to study its derangements in various phases, but for experimental research leading to a rational therapy. The time has now, indeed, arrived in which it may be not rashly asserted that one might as readily attempt to diagnosticate a grave kidney-derangement without an examination of the urine, as some of the common gastric ailments, without at least a cursory study of the secretory condition of the diseased stomach. Beyond doubt, less hazard will result from such empiricism applied to the management of derangements of the kidney than to that of those of the stomach, the constant disorder of which may be regarded as *fons et origo* of many of the chronic ills that appear with increasing years. Fortunately, the use of the tube for diagnostic purposes, and the subsequent examination of the removed stomach-contents, require so little special skill that these are the reach of even the medical tyro.

The best form of stomach-tube is that of Ewald. This is of moderately soft red rubber, of open and somewhat tapering tip. It has in the lateral walls one large fenestra, and a number of smaller ones.[1]

The tube of Ewald, as sold, is of insufficient length for lavage. When used for this purpose, a second portion of gum tubing must be joined by the interposition of a small section of glass piping. For a mere removal of the stomach-contents the length is ample without the second piece of tube, except in cases of gastrectasis.

So important an adjuvant to diagnosis and treatment is the tube, that I consider it almost impossible to do justice to a case of pronounced chronic gastric disorder without a resort to it in some stage of the disease. So helpful is it in arriving at a correct diagnosis, and in directing the therapy, apart from its utility for lavage, that the earlier a patient can become habituated to its employment the better. I now rarely treat a case without it, and as rarely encounter one that will not willingly consent to its use for diagnostic purposes and treatment, when its utility is explained. But a few introductions of the tube are required—the throat cocainized[2] at first, if necessary, and the intervals not too

[1] Einhorn advises from one-half to one pint. Heryng and Reichmann (Therapeutische Monatshefte, March, 1892), who have recently investigated gastrodiaphany with a special apparatus of their own, find that the most satisfactory results are obtained when the stomach is *filled* with water. They use, according to the degree of dilatation, from 500 to 2000 c.cm. My own experiments with Einhorn's gastrodiaphane have given me much better results when the stomach was distended with water.

[2] As it is usual to examine the gastric contents in cases in which diaphanoscopy is indicated, the patient has probably become somewhat accustomed to the application of the soft tube. This I regard desirable when it can be arranged, as nervousness and gastric irritability will not then disturb the examination.

[3] Einhorn relates a case of probable diffuse carcinoma, in which the diagnosis was so established.

[1] The inner edge of the large opening in the lateral wall should be bevelled. Even with the 11 mm. tube, the full size, I often have had difficulty in removing the stomach-contents after a general meal, in which imperfect solution of the food has occurred. Large portions of mucus alone will sometimes block both the tip and lateral fenestræ. Cheaper, softer tubes than Ewald's are generally sold in this country. These are of red rubber, about 60 inches in length. They have an open tip, and a fenestra in the lateral wall. Their other extremity is made funnel-shaped.

[2] A small quantity of a low percentage of cocaine (about 3 to 4) is projected with a medicine-dropper upon the posterior pharyngeal wall, shortly before the tube is passed. I always make use of cocaine in this way, especially in women, the first two or three times. Subsequently cocaine may be dispensed with. The gummy smell of the tube, after introduction, is offensive to some, and may in itself produce nausea. A few drops of mentholated oil snuffed into the nostrils disguises this. After a few introductions the odor is no longer objectionable. After cocainizing the throat the stomach extremity of the tube is rapidly

lengthy—before the patient will most readily manipulate it totally without inconvenience, and always, in selected cases, with benefit.

The stomach-contents are more readily removed with less disturbance to the patient by aspiration than by the expression method of Ewald, now commonly recommended. The latter is often difficult of successful application in uneducated cases, and is, moreover, annoying to the patient. Frequently, also, by it the entire stomach-contents cannot be removed, so necessary for a complete examination when a small meal, such as a trial-breakfast, has been taken. There is also likelihood of a reflux from the duodenum of alkaline juices in cases of relaxed pylorus, when straining efforts of evacuation are made, besides the actual danger of hemorrhage in cases of unsuspected ulcer. I now invariably use for aspiration a simple apparatus, which can be readily made by anyone. It consists of a wide-mouth bottle of moderate capacity, with a rubber stopper containing two perforations, holding glass tubes, the outer extremities of which are bent at a right angle; to these are attached the stomach-sound and a simple rubber bulb, or, preferably to the last, an ordinary enema syringe, minus its metal or hard-rubber extremity. With the bulb or syringe a rapid exhaust of air in the bottle is produced, the latter being held below the stomach-level. A prompt inflow of gastric contents then usually promptly occurs without gastric disturbance. Should the flow not occur promptly, or, having begun, have ceased, the intra-gastric extremity of the tube being at the fundus, the exhaust syringe should be reversed, and several bulbfuls of air pumped into the stomach. Thus, any food particles or masses of mucus which may have blocked the fenestræ will be dislodged. The syringe is then reversed and the aspiration completed. The bottle, stopped with an ordinary cork, serves to transport the stomach-contents, should the aspiration have been done away from the place of examination.

Many and careful studies of the gastric secretory function during fasting and in various periods of digestion, first undertaken by Ewald and Boas, and subsequently pursued by many others, with results in the main confirmatory of those obtained by the former, have shown that normally during fasting the stomach contains no digestive secretion;[1] and that after food, certain definite stages of digestion occur, during which, with very similar quantity and character of aliment, similar intra-gastric conditions will be encountered, and that if broad deviations occur from these an abnormality is indicated. A variety of trial-meals have been suggested to ascertain this, such as Ewald's, Leube and Riegel's, Reichmann's, and Jaworski's,[1] any one of which resorted to, must invariably be ingested on an empty stomach. Whichever is selected, it is desirable that that one only should be habitually used, as different varieties and quantities of food do not stimulate the secretory function equally.

The stomach-contents should be removed at a time when digestion is normally at its height, which occurs after Ewald's breakfast in from three-quarters of an hour to one hour; after Riegel's meal in from three to five hours, and in about one and a half hours after Reichmann's.

During the early stage of the digestive phase the acidity of the gastric contents is feeble, due to acid salts of the ingesta, and to lactic acid, the latter derived either from the lactates in the food or from fermentation of carbohydrates. In this stage, varying from twenty minutes to two or more hours, depending upon the amount and character of the ingesta, saccharification of starch, begun in the mouth, occurs, and continues so long as the acidity due to organic acids and acid phosphates remains at a minimum. The second stage is characterized by the appearance of uncombined HCl, after complete saturation by the latter of organic bases and albuminoids.[2] Free HCl now gradually increases in amount until the normal percentage—0.15 to 0.3[3]—is reached, while lactic acid and acid salts coincidently diminish, and finally disappear,

passed toward the pharynx, the patient being directed to swallow as it engages in the latter. With one or two efforts at deglutition the tube can then usually be pushed rapidly onward until it reaches the stomach's fundus. It is unnecessary to introduce the finger into the mouth in passing the soft tube, guidance past the epiglottis not being required. The whole maneuver, introduction of tube and siphonage, can be accomplished usually in a few seconds.

[1] Apparent exceptions to this exist only in those in whom manipulation excites a flow of gastric juice, or, in cases of hypersecretion, in which, during fasting, the stomach often contains more or less gastric juice, the acidity of which is often higher than that of the normal.

[1] That in common use is Ewald's, consisting of a well-cooked stale roll (or 35 to 70 grams of stale white bread), without butter, and 300 c.cm. of water, or an equal quantity of weak tea without milk or sugar.

Leube and Riegel's dinner, of which the other trial-meals are modifications, consists of 400 c.cm. of soup; 60 or more grams of scraped beef; 50 grams of white bread, and 200 c.cm. of water. It is less convenient of administration than Ewald's, and is likely to be much more difficult of removal than the others, when digestion is retarded.

Reichmann's breakfast consists of 30 grams of meat-powder; 2 grams of salt; 200 c.cm. water, and one wheaten roll.

Jaworski uses the whites of two hard-boiled eggs, and 100 c.cm. of water.

[2] By free HCl is meant that not united as a salt with the organic bases of the ingesta, or loosely combined with the albuminoids. The latter represents the bound or united HCl, not detectable by qualitative tests. See my paper in Hare's System of Therapeutics, vol. ii, p. 890.

[3] 0.3 per cent. of free HCl is often present physiologically at the height of digestion of a full meal.

except in traces too minute to be appreciable by ordinary tests.

After a light meal, such as Ewald's trial-breakfast, the reaction for free HCl is usually manifest to ordinary tests in from twenty to forty-five minutes, and at the latter period in the percentage stated. At the height of digestion of a more varied meal the percentage of free HCl may be even greater than this normally; and contrarily, in diseased conditions may also be much less, depending upon the readiness with which the secretory function responds to increased stimulation. The reaction for starch is then normally absent, but that for erythrodextrin and grape-sugar is decided. Tests for ordinary albumin also result negatively, while, contrary to what is ordinarily regarded as the rule, there is an abundance of proteoses, but traces only of peptone, if present at all. The formation of abundant proteoses (albumoses) indicates sufficiently the presence of pepsin, while the existence of lab-ferment is evinced by the ability of the filtrate of the removed contents to solidify milk.

A systematic examination of the gastric secretion is best conducted as follows:[1] The stomach-contents, removed at the time already specified, are carefully inspected as to the presence of blood, bile, mucus, and evidences of solution of food. It is now subjected to thorough agitation in a small vial, preceding filtration, if the latter is practised, as it has been ascertained that different portions of the filtrate are sometimes of varying acidity.[2] Examination should be made as early as possible after removal of the contents, that further digestion or fermentative processes may not ensue, perhaps resulting in disappearance of the free HCl present.

The acidity is first ascertained by litmus or Congo paper.[3] Congo paper may be first used, since, because of its reacting to free acids and abnormal amounts of acid salts, rendering blue or violet the former and weakly browning the latter, a positive response obviates the use of litmus, and often gives valuable preliminary testimony.

The total acidity—that due to free acids and acid salts—is now determined. Ten c.cm. of the stomach-contents are titrated with a deci-normal solution of sodium hydrate,[1] a drop or two of a weak alcoholic solution of phenol-phthalein being first added as the indicator. A persistent, very faint red tinge shows neutralization. The total acidity is calculated on 100 c.cm. of stomach-contents. One hour after Ewald's trial-breakfast this should be between 20 and 60, equaling an acidity which, if due to HCl alone, would represent 0.07 and 0.21 per cent.

The presence of acid salts or free acids, may be determined by Congo paper as already stated, but, more delicately, by Leo's $CaCO_3$ test. A few drops of the filtrate are thoroughly mixed in a watch-glass with a little dry powdered $CaCO_3$ (C. P.).[2] After complete neutralization of the free acids of the filtrate, and disappearance of dissociated CO_2, the reaction is taken with blue litmus paper and carefully compared with that of the original unneutralized filtrate. A simple *lessening* of red coloration shows the presence of both free acids and acid salts. Its total disappearance indicates positive absence of acid salts.

In examining for free HCl only those tests should be employed which respond to a mineral acid. For this reason Congo, methyl-violet, benzo-purpurin, 6 B., tropeolin (00), and other similar color reagents and combinations are not to be preferred to Günzburg's or Boas's[3] solution. Of these last, Günzburg's solution is a trifle more delicate; and as it may also be employed for the quantitative

[1] Lack of space prevents the subject being here considered other than in outline. It is, however, sufficiently detailed for practical clinical purposes.

[2] See "Die Magensaüre des Menschen," Martius and Lüttke. For this reason it is advisable to make quantitative examination for HCl and for the acidity, without filtration. When filtration is practised, thorough agitation should first be made. I have recently applied the centrifugal machine used for prompt separation of precipitates in urine, for quickly obtaining the fluid portion of the stomach-contents, after thorough shaking to insure an equable mixture.

[3] Congo paper is more convenient for use than Congo solution, though also much less delicate in response to free acids. Of the solution, a droplet added to a drop or so of the gastric filtrate, develops a violet or blue coloration depending upon the amount of free acid present—violet, if a minimum. 0.001 HCl and 0.002 lactic acid in *aqueous* solution are thus shown with certainty. With Congo paper but 0.01 HCl and 0.03 lactic acid respond to similar solution. See Leo: Diagnostik der Krankheiten der Verdauungsorgane, p. 92.

[1] $\frac{N}{10}$ NaHO = 4 grams NaHO dissolved in 1000 c.cm. distilled water. Each c.cm. of this solution exactly neutralizes 0.0036 grams absolute HCl. The number of c.cms. consumed in the titration, multiplied by 0.0036, would represent the percentage of HCl contained in 100 c.cm. of the gastric filtrate, if the only acid present were HCl. The titrating solution is slowly dropped, with constant stirring, from a burette graduated in one-tenths of c.cm.

[2] $CaCO_3$ in cold solution neutralizes free acids only, not reacting with acid salts. This test is very delicate. Its application, after removal of fatty acids by heat, and lactic acid by agitation with ether, is the most certain and sensitive test known for free HCl. According to Leo, 0.002 per cent. of the latter may be detected by it if decided amounts of acid phosphates are not present; even then 0.008 per cent. HCl may be shown with exactness.

[3] Günzburg's solution spoils more readily than Boas's. It should be prepared only in small quantities, and kept in a black, tightly-stopped bottle. Boas's solution consists of re-sublimed resorcin (5), sugar (3), dilute alcohol (100). Its application is identical with that of Günzburg's. Should response to Congo paper not occur, it may be necessary to gently evaporate several drops of the filtrate to obtain a reaction with these tests, and then but a fleeting red at the circumference may be produced, denoting minute traces only of free HCl. For percentage of delicacy of response of these tests and interference therewith in other solutions than aqueous, see my paper, Hare's System of Therapeutics, ii, pp. 897, 898; and Leo, loc. cit., p. 93 et seq.

determination of free HCl (Mintz method) it is to be selected. Günzburg's solution consists of 1 part of vanillin, 2 of phloroglucin, and 30 of absolute alcohol. One or two drops of the gastric filtrate, with one of the test-reagents, are gently heated over an alcohol or Bunsen flame on a porcelain dish. On slight evaporation, a delicate rose-red tinge appears at the margin of the liquid, and promptly becomes of an intense cherry-red, depositing minute crystals of a similar color in the presence of decided amounts of free HCl. With the usual percentage of free HCl present, one drop of gastric filtrate may be diluted upward of fifteen times, and yet a drop of this dilution will be found to respond to freshly made Günzburg's solution.

Freshly prepared Günzburg's solution forms an easily applied quantitative test (Mintz's)[1] for free HCl which is sufficiently exact for clinical purposes. Ten c.cm of the filtered or unfiltered stomach-contents are carefully titrated with deci-normal soda solution from a burette until a response no longer occurs with Günzburg's reagent. With the addition of each $\frac{1}{10}$ c.cm. or fraction thereof, depending upon the amount of free HCl suspected to be present, a drop or two of the partly neutralized contents is tested with Günzburg's solution.[2] The limit of the Günzburg's reaction being approximately 0.036 pro mille of HCl, an estimation of the percentage of free HCl is made by the multiplication of the number of c.cm. and fraction thereof at which the response just ceases, by 0.0036.

Examination for organic acids—lactic and fatty.[3] —Lactic acid is detected by the addition of a few drops of the gastric filtrate to Uffelmann's carbolated ferric chlorid solution,[4] or to a very dilute solution of ferric chlorid[5] alone, in a test-tube; the amethyst-blue color of the former solution is at once transformed into a yellow, and the light, almost colorless, yellow of the latter will be intensified in the presence of traces of lactic acid. Unfortunately, glucose, acid salts, and lactates also respond to the carbolated ferric chlorid test, and lactates and peptone to its modification, the ferric chlorid. A positive reaction occurring, therefore, a second step is necessary. A small quantity of the filtrate—about a dram—should be thoroughly agitated in a test-tube or separating funnel with about three or four times this amount of neutral ether. When great delicacy of result is especially desirable, as in removing all traces of lactic acid prior to testing for free HCl by calcium carbonate, several fresh portions of ether should be used. The ether is on each occasion removed by a pipette, if a separating funnel has not been employed for agitation. It is subsequently evaporated on a capacious watch-glass or porcelain dish, on a water-bath or in the air, and an aqueous solution of the ethereal extract tested by Uffelman's solution, which with these precautions becomes the most delicate reagent for the detection of lactic acid.

The fatty acids may be very simply detected by heating to the boiling-point a few c.cm. of the filtrate in a test-tube, over the mouth of which is suspended a strip of moistened neutral or blue litmus paper. Traces of these acids may be thus recognized.

The presence of free HCl indicates, beyond doubt, also the presence of pepsin. In the absence of response to tests for the former, the presence of the milk-curdling ferment also signifies the existence of pepsin. Response to the digestive test is also a certain indication of the secretion of both pepsin and HCl. A small disc of hard-boiled white of egg, or a similar quantity of purified blood-fibrin[1] is placed in one or two drams of the filtrate in an incubator maintained at a temperature of about 100° F. The albumen should be dissolved in from one to three hours, if pepsin and the normal percentage of HCl are present. If absence of or a deficiency in HCl exists, this acid should be added until, roughly, a percentage of from 0.1 to 0.3 is reached.

The presence of proteoses (albumoses or propeptones) also indicates the presence of peptone, for, although HCl alone apparently possesses the power to form a small amount of proto-albumose as well as syntonin, its secretion without the coincident appearance of pepsin seems impossible.

Until recently it was thought that peptone was formed in abundance in the stomach, as a result of pepsin-HCl digestion, and that this, indeed, was the true end-product of the same. The researches

[1] Mintz: Wiener klin. Woch., 1889, No. 20; 1891, No. 9; and Martius and Lüttke's Die Magensaüre des Menschen, pp. 90, 91.

[2] If Mintz's test is applied after the total acidity is reckoned, and an account has been taken of organic acids and acid salts, an approximate idea may be formed of the quantity of soda solution required, so that too frequent repetition of application of Gunzburg's test may be avoided during titration. If, however, only a small quantity of stomach-contents is obtainable, the test may be at once applied in the manner directed to the 10 c.cm. from which the total acidity is calculated, great care being then observed in the addition of the neutralizing solution.

[3] Space does not here permit detail of methods for estimating both the combined and free HCl, less necessary of calculation than the latter alone. Unfortunately, of the many proposed and in use, none is without elements of fallacy; those that are regarded as freest from error, and which I usually employ, are Salkowski's modification of Sjöqvist's method (Zeitschrift f. physiolog. Chem., 1888; Bd. 13) and Leo's (see his Diagnostik, etc. or Martius and Lüttke's Magensaüre).

[4] A dilute solution of neutral iron chlorid containing a drop of carbolic acid.

[5] So dilute as to be almost colorless. For comparison of result, a second test-tube is filled with a similar solution to which an equal quantity of water is added, as of filtrate to the first. The colors of the two are carefully compared.

[1] Blood-clot is repeatedly washed until all trace of blood-coloration is removed. It is then preserved in glycerin, which latter is first removed from the test-portion used, by repeated washings.

of Kühne and Chittenden[1] tend to indicate that this is not the case; that but a minimum amount of true peptone is actually formed even through the long-continued action of pepsin-acid.[2] Bodies intermediate between syntonin and peptone seem to be largely the actual final product of peptic digestion, if one may judge by the relative amount of these and of peptone formed. The proteoses or albumoses are at least three, pro-albumose, hetero-albumose, and deutero-albumose; each of which in the order named progressingly approaches peptone. After neutralization of the acid filtrate, which precipitates syntonin or acid-albumin, and the removal of the latter, it had been thought, until Kühne and Chittenden's observations showed the contrary, that the primary products of digestion could be removed by the addition of sodium chlorid and strong acetic acid. Recently these experimenters ascertained that at least deutero-albumose is not thus precipitated, and that even proto-albumose and hetero-albumose are incompletely precipitated unless the sodium chlorid be present to saturation—so that the body termed "peptone" in the past has been variously deutero-proteose alone or a mixture of the proteoses, or of proteoses and peptone.

At the height of normal gastric digestion, one hour after Ewald's trial-breakfast, little or no cloudiness should occur on boiling and on neutralization of the gastric filtrate, showing absence of undigested albumin and of syntonin. These, if present, are removed by filtration. The colorless filtrate may then be at once acted upon by *neutral* ammonium sulphate, which in hot saturated solution almost entirely removes all traces of the proteoses; or, the filtrate may be first treated with cold saturated solution of sodium chlorid and strong acetic acid, which precipitates proto-albumose and hetero-albumose. Finally, deutero-albumose and traces of the other albumoses remaining may be precipitated by saturating the neutralized filtrate while hot with ammonium sulphate. The resulting ammonium sulphate filtrate should then be examined for peptone by the biuret test.[3]

In a considerable number of tests for peptone so applied, at the height of gastric digestion, my experiments are confirmatory of the test-tube experiments of Kühne and Chittenden. I have, indeed, rarely found more than traces of peptone, and frequently have been unable to obtain the biuret reaction in subjects in whom the digestive secretion otherwise responded normally. In these, proteoses were present in abundance, with no traces of undigested albumin and but little syntonin.

The presence of the milk-curdling ferment—an enzyme apart from pepsin and not related to HCl[1]—is readily ascertained by the addition of a few drops of gastric filtrate to about a dram of unboiled milk; this placed in a warm chamber solidifies in from a few minutes to an hour.[2]

Starch is readily detected in the stomach-contents by the blue coloration resulting when the filtrate is tested with Lugol's solution. The presence of erythrodextrin, a primary stage in the conversion of starch into maltose, is shown by a purple or brown hue developed. Achrodextrose, maltose, and dextrose, more advanced stages of the hydrolysis of starch, do not react to solutions of iodine. It is useless to test for grape-sugar, as this preëxists in the roll eaten.

The estimation of the propulsive functions of the stomach is of great diagnostic, prognostic, and therapeutic importance. It is most conveniently tested by salol, the method of Ewald and Sievers. This method furnishes fairly accurate results and is readily applied,[3] unlike the method, proposed by Klemperer, with oil. It is, however, unfortunate that hyperacidity due to increased secretion of HCl, which often occasions and accompanies gastric hypermotility, may cause delay in the intestinal decomposition of salol, and thus mislead, the result of the test suggesting the reverse condition—hypotony. Therefore, in instances of hyperacidity with delay in salicyluric acid response, in which a study of the propulsive function is of importance, Leube's method also should be tried—that of washing out the stomach and inspecting the removed contents for food elements from six to seven hours after a trial-dinner, or two hours and a half after Ewald's trial-breakfast, at the expiration

[1] See Chittenden: "On the Relative Formation of Proteoses and Peptones in Gastric Digestion." Journ. of Phys., vol. xii, No. 1.

[2] Unlike what occurs in consequence of pancreatic digestion of albuminoids, as a result of which peptone is readily formed without the intermediate albumose stages.

[3] The filtrate should be treated with a sufficient quantity of a strong potasium hydrate solution to decompose all ammonium sulphate present (see Chittenden, loc. cit.). Succeeding this, a drop or two of a very weak cupric sulphate solution should be added. The presence of peptone is shown by a purple-red color, varying to bluish-violet, depending upon the amount present.

[1] The characteristic solidification of milk under the action of the ferment rennin must not be confounded with the fine, flaky coagula resulting from acids.

[2] Should coagulation not occur at the expiration of the specified time, rennin is probably absent, though its pro-enzyme, lab-zymogen, may not be. A small quantity of concentrated solution of $CaCl_2$ is added to the mixture, which is again placed in a warm chamber. Solidification now resulting indicates the existence of lab-zymogen, which, through the action of the $CaCl_2$ added, generating HCl, is transformed into the active ferment.

[3] Fifteen grains of salol in water are administered shortly after an ordinary meal. The urine is tested for salicyluric acid, beginning half an hour after the ingestion of the dose, and continued at intervals of from fifteen to twenty minutes, until response occurs. A simple method is to moisten strips of filter paper with a few drops of urine, touching the moistened spot with a few drops of a 10 per cent. solution of iron chlorid. A violet color indicates the presence of even traces of salicyluric acid. This reaction occurs normally in from forty to seventy-five minutes.

of which period the stomach should be empty. The condition of the absorbent function of the stomach, of much less importance than the propulsive or secretory, is ascertained by the method of Penzoldt and Faber. Two or three grains of potassium iodid, inclosed in a gelatin capsule, the exterior of which must contain no traces of the salt, are ingested with a little water, on an empty stomach.[1] Normally, rapid absorption of the iodid from the stomach occurs, iodine being detected in the saliva in from six to fifteen minutes. Strips of starch-paper[2] are moistened with the saliva and then a drop of fuming nitric acid is added to the moistened spot —a bluish coloration shows the presence of iodine.

Of the three gastric functions the trend of opinion recently is toward regarding the propulsive as the most important. Diminution in it, however perfect the gastric chemism, is likely to lead to impaired nutrition and secondary secretory disturbance far more promptly and more frequently than is a mere diminution in chemism to affect gastric motility. The chief function of gastric digestion is that of peptonization of proteids, and yet, as has just been stated, true soluble diffusible peptone is, under the most favorable circumstances, formed to a very limited extent in the stomach, bodies intermediate between it and acid-albumin being largely the end-products of pepsin-HCl digestion. These are but slightly absorbable, dialyzing and diffusing with difficulty. Subsequently, through tryptic digestion, the proteoses are converted into soluble peptone. Carbohydrates, save that portion acted upon by the saliva and fats, are also subject to intestinal digestion. Milk is coagulated and subsequently partly peptonized in the stomach; but since a milk-curdling ferment is also secreted by the pancreas, the stomach may be said to possess no digestive function not existing in the pancreatic juice.

Proteolysis, the chief digestive function of the stomach, is so much more efficiently performed by the pancreatic juice, which also readily digests starches and fats, that the gastric secretory functions may be in entire abeyance for long periods, and almost perfect bodily nutrition maintained by duodenal digestion, provided the gastric motility remains normal. It must, however, be borne in mind that derangement of the secretory apparatus tends, as a rule, if prolonged, to lead to atony of the stomach, and this eventually to a catarrhal condition which may eventuate in atrophy of the gastric tubules. In this condition degeneration of the gastric muscle is likely to occur.[3]

[1] For more detailed account of estimating gastric motility see my paper in Hare's System of Therapeutics, vol. ii, p. 900 et seq.

[2] Filter-paper saturated with starch paste, and dried.

[3] Cases of this sort are not uncommon, though few have been reported, except in Germany. I have had one—a woman—under observation for a year and a half. Einhorn (Med. Record, June 11, 1892) reports four cases of so-called atrophy of the stomach—but for which he suggests the term *achylia gastrica*—under his notice for several years. Three of these remain well nourished. One is a robust male, aged forty years, in whom Einhorn believes the anacidity has probably existed from earliest youth.

The various disorders affecting the stomach are characterized by an alteration in one or all of the functions, the recognition of the condition of which has just been considered. Derangement of gastric chemism is the most common. The secretory alteration consists especially in either diminution or increase in the most important of the constituents of the gastric juice—hydrochloric acid. Diminution is usually accompanied by a lessening in the production of pepsin and rennet ferment, though these latter or their pro-enzymes[1] are never habitually absent from the gastric secretion, except in advanced atrophy of the mucosa, in which condition the secretory function is, of course, totally in abeyance. Unlike the case with secretion of pepsin and rennet ferment, free HCl may be completely unrecognizable in various affections, such as carcinoma of the stomach,[2] and less often, though more frequently than is commonly supposed, in certain gastric disorders depending upon a neurosis and of reflex origin.

Diminution or even absence of HCl in the stomach sometimes occurs solely as a neurosis, in the hysterical and neurasthenic, and as a reflex gastric disturbance in many uterine disorders and during menstruation. Cases are also rarely encountered in which, with presumably a normal mucosa, and without evidences of ailments affecting the stomach reflexly, in which free HCl is much diminished or absent. Diminution in secretion of HCl also attends all acute febrile conditions, acute or chronic gastric catarrh,[3] whether primary or secondary to heart, lung, or other visceral disease, or to gastric dilatation.

[1] Pepsin and rennin probably do not exist in the secreting cells as active ferments, but as pro-enzymes, which are subsequently converted into the former by the action of certain substances, such as common salt and HCl.

[2] Absence of free HCl in carcinoma of the stomach results from disturbance in the secretory function, originated in all probability by an accompanying gastritis, leading to generalized atrophy of the mucosa. Rarely, free HCl persists until death, despite the presence of carcinoma, and very exceptionally, especially in carcinoma originating from ulcer, free HCl is present in excess. In these cases the gastric mucous membrane, except in the immediate vicinity of the cancer, has been found normal, *post-mortem*.

[3] An apparent exception exists in cases of hypersecretion of HCl, in which a catarrhal condition of the mucosa may be produced by irritation of the highly acid gastric juice. This continuing, chronic gastritis with subacidity ultimately results. Occasionally, also, in cases of simple mucous catarrh in which probably no structural alteration in the specific secretory epithelium has yet eventuated, periods of plus secretion in HCl replace diminution in the same. This last, though contrary to the teaching of Ewald, is based on positive evidence in cases that I have carefully studied.

Diminution in, or absence of, secretion of HCl is often accompanied by the presence of large amounts of organic acids and acid salts in the stomach; especially is this the case if lessened gastric motility permits undue retention of food; so that in chronic gastric catarrh and in gastrectasia, however arising, these acids are usually found in abundance at a stage of digestion in which free HCl should be the only acid detectable by tests commonly employed.

Hyperacidity of the stomach may be due to the undue presence of organic acids arising through fermentation of food. This condition is often encountered in gastric catarrh, dilatation, and carcinoma. Hyperacidity more commonly occurs as a neurosis, it being then due to the presence of an excessive amount of free HCl, in which condition organic acids are at a minimum. Hyper-HCl production may or may not be accompanied by hypersecretion. When the latter is present, many ounces of an active digestive fluid may be obtained from the fasting stomach, even when little or no manipulation has been used in its extraction. Hypersecretion of gastric juice may or may not be accompanied by hyperacidity, though it usually is. It occurs either continuously, in which condition many ounces may be obtained from the fasting stomach, or periodically, and then especially after the ingestion of food.

SYMPHYSIOTOMY VERSUS ITS SUBSTITUTES; WITH THE REPORT OF A CASE OF SYMPHYSIOTOMY.[1]

BY CHARLES P. NOBLE, M.D.,
SURGEON-IN-CHIEF, KENSINGTON HOSPITAL FOR WOMEN, PHILADELPHIA.

THE revival of symphysiotomy is due to the genius of Morisani, of Naples; its introduction into the United States, to our distinguished Fellow, Dr. Robert P. Harris. Now that the results of symphysiotomy are known, as accomplished by the operation done under modern aseptic methods, the wonder is that the profession could have been blinded by the prejudices of the past, arising out of the comparative failure of the operation when done without regard to a knowledge of scientific obstetrics or surgery.

The results obtained by Italian operators under the influence of Morisani's teachings took the world by surprise. The fact that the work was being done was well known, but the profession was supercilious and refused to estimate it in a scientific spirit. The old, prejudiced belief that symphysiotomy was necessarily a failure, because it did not permit of an increase in the conjugate diameter of the pelvis, and because it jeopardized the integrity of the pelvic symphyses, was too firmly grounded to be easily set aside, and it required the demonstration of the safe delivery of thirty women, in Italy, having contracted pelves of marked type, before any but Italian surgeons were willing to perform the operation.

The old objections to the operation were: 1. That in contracted pelves, as a rule, the antero-posterior diameter is the shortened diameter; and that this diameter is scarcely, if at all, increased by the operation. 2. That there is great danger of rupture of the sacro-iliac symphyses. 3. That the symphysis pubis would not unite properly; and hence that the powers of locomotion in women subjected to the operation would be greatly lessened. Experience has shown each of these objections to be groundless or much overstated. Undoubtedly the oblique and transverse diameters of the pelvis are increased more than the antero-posterior, but this diameter also is increased. When the pelvic bones are separated from two to two and a half inches, enough room is afforded for the rounded head (perhaps the parietal protuberance) to project into the opening, thus increasing the working space at least half an inch. This increase in space, together with the increase in the oblique diameters, affords the necessary room for delivery, except in cases of very marked deformity.

The objection that the sacro-iliac joints may be ruptured has not been borne out by experience. Nevertheless it should not be forgotten that at times the pelvic joints are ruptured in cases of difficult labor in which symphysiotomy has not been done. This should admonish surgeons to be careful in recommending the operation in cases of marked deformity, especially if the head of the child seems large and well ossified.

The final objection, that the divided symphysis would not unite, is likewise not well founded, as experience has demonstrated that it unites with pleasing uniformity and facility.

Since January 8, 1886, there have been fifty-seven symphysiotomies, and all the women have recovered, except one. This woman (case of Martino, September 22, 1886) had been in labor several days when operated upon, and died of metro-peritonitis, due to infection of the birth-canal, and not to the operation. This fact justifies the conclusion that in proper cases when done early, and after the antiseptic method, symphysiotomy has no mortality. This is true, however, only under the conditions laid down. The history of the operation admonishes us that when done on improper cases, and without asepsis, its mortality is high.

The complications following the operation have been urethral and vesical fistulæ in a few cases. According to Morisani, these were due to a faulty technique. Not having had the opportunity myself to study the recorded cases of symphysiotomy, to

[1] Read before the College of Physicians of Philadelphia, Feb. 1, 1893.

discover accidents resulting from it, I wrote to Dr. Harris, who has recently studied the literature in the preparation of his paper on the subject (*Trans. Amer. Gynecological Society*, 1892). He writes me that since the perfection of the technique, in 1886, there is no case recorded in which the sacro-iliac joints have been injured; no case in which a child has been delivered absolutely dead; and no case in which it was necessary to practise embryotomy to complete the delivery. Even going back to 1866, in 125 symphysiotomies there is but one case recorded of possible injury to the sacro-iliac joint. This was a case of iliac phlegmon, which is by no means necessarily due to joint-injury.

The results to the children delivered by symphysiotomy have been equally good. No child has been born absolutely dead, but six children out of fifty-seven died shortly after birth.

Having thus disposed of the questions heretofore raised concerning the operation, it remains to consider its true field of usefulness and its relation to Cesarean section, the induction of premature labor, and to embryotomy.

The operation has been done, heretofore, principally in cases of flat pelves, and the measurements hereafter given refer to that deformity. Other varieties of deformity are rare, but fortunately the operation is even better adapted in them to facilitate delivery, excepting cases of Naegele or Robert pelves.

The conjugate diameter in the women heretofore operated upon has varied from 66 mm. ($2\frac{5}{8}$ in.) to 97 mm. ($3\frac{13}{16}$ in). There is a general agreement among surgeons to limit the field of symphysiotomy in flat pelves to cases having at least $2\frac{3}{4}$ inches in the conjugate diameter. I find myself in agreement with this opinion. My own experience in delivering a child weighing eight pounds and two ounces through a pelvis of $2\frac{3}{4}$ inches has admonished me that less room would entail very great danger of death to the child, and would put more strain on the sacro-iliac joints than would be judicious.

In this field symphysiotomy comes directly into competition with the Cesarean operation, done for the relative indication. I am convinced of the beneficent nature of the modern Cesarean operation, when done *secundem artem*, and that it has a very low if not a *nil* mortality in the hands of an expert. Nevertheless, it must be acknowledged that the Cesarean operation is a more formidable operation than symphysiotomy, and that its possibilities of morbidity and mortality are undoubtedly greater. Hence I unhesitatingly pronounce in favor of symphysiotomy in this field, and believe that it will soon supplant the Cesarean operation performed for the relative indication. Aside from its absolute claims for preference, there are several relative claims which I believe will prove of great service in practice. The practitioner will not have to overcome a popular prejudice, as is the case with the Cesarean operation. Symphysiotomy is to the public a new operation; hence the public is prepared to estimate its risks as presented by the profession. This is not true of the Cesarean operation, for the modern operation has to bear the evil name of the old operation, and is believed by the public to be almost necessarily fatal. These considerations will render it more easy to gain consent for the performance of symphysiotomy than it has been for the Cesarean section. Another advantage will be that the failure of the natural forces, assisted by art, to accomplish delivery, will prove a convincing argument in favor of the necessity for symphysiotomy. And, happily, the operation can then be done with success, whereas, in the case of the Cesarean operation the favorable time would already have passed by.

Symphysiotomy likewise fills the field heretofore occupied by embryotomy done on the living child. Since the perfection of the technique of the Cesarean operation, in common with many others, I have denied the justifiability of embryotomy done on the living child. With the addition of symphysiotomy to scientific obstetrics I believe that the slaughter of the innocents will cease. The old excuse for embryotomy, that it is justifiable to kill the child to save the mother, no longer holds, for both can be saved either by the Cesarean operation or by symphysiotomy. As I have recently discussed this phase of the subject in a paper read before the Philadelphia County Medical Society (*Amer. Journ. of Obstet.*, 1893) entitled "Cesarean Section and its Substitutes," I have only to add that I believe the greatest good which will be accomplished by symphysiotomy will be that it will put a stop to the killing of unborn infants. Courageous and expert surgeons could save both mother and child by the Cesarean operation, but apparently they could not do away with the practice of embryotomy.

Symphysiotomy, also, has been performed in the same classes of pelves in which, heretofore, the induction of premature labor has been practised. Hence these two operations come into competition. This is a phase of the subject which heretofore has attracted no attention. This fact renders it inexpedient to dogmatize at this time. But I believe that symphysiotomy is destined to supplant the induction of premature labor, especially as a hospital operation and in practice among the ignorant and the poor. Embryotomy heretofore has been employed to terminate arrested labors amongst the poor having deformed pelves. Such people, as a rule, employ midwives or physicians who do not devote much study to their cases prior to the onset of labor. As a result premature labor is seldom induced among this class in private practice. Sym-

physiotomy will now supplant embryotomy among them.

In hospital practice the choice of operation will depend on the mortality of the mother and the child under the two operations. The advantages appear to be decidedly on the side of symphysiotomy. The maternal mortality from the induction of premature labor is variously stated by authorities. For example, according to Wyder's statement 5 per cent. of the mothers and 50 per cent. of the children die. Winckel states that of children born at from seven and a half to eight months only 33 per cent. are actually kept alive. Under the use of the incubator at the Leipzig maternity there was an infant-mortality of 18 per cent. in the hospital, and at the Paris Maternité there was a mortality of 30 per cent. It is also well known that the mortality of premature infants among the poor is very high in the first year of infancy, so that Winckel's estimate is probably correct.

In my judgment 5 per cent. is an excessive estimate of the maternal mortality of the induction of premature labor. One per cent., or certainly 2 per cent., should cover the mortality in careful hands.

The showing under symphysiotomy is much better. The maternal mortality is zero, and the fetal mortality is six in fifty-seven, or less than 11 per cent. The chances of the mature child delivered under symphysiotomy to reach maturity are likewise far greater than those of the immature child delivered about the thirty-fourth week of gestation. This is especially true of the children of the poor.

Among the intelligent and well-to-do, premature labor will probably be elected for a time; but if symphysiotomy continues as successful as it promises, it will supplant the induction of labor even in this class of cases. Intelligent people will not care to run the risk of losing their children from prematurity, or, what is worse, having them suffer from hydrocephalus (which is common in such children), and from various neuroses, if a mature child can be delivered with less risk to the mother under symphysiotomy.

The technique of the operation can be considered conveniently in connection with the report of a case of symphysiotomy which follows.

Mrs. X., the subject of this report, is a small woman, weighing one hundred pounds. She is thirty years of age, and has had five children, the last of which was delivered by symphysiotomy. A complete history of her five labors would be a fairly full consideration of dystocia due to deformity of the pelvis, together with the obstetric procedures used to complete such unnatural labors. The following are the measurements:

Height, 4 feet, 8 inches. A. S. S., 24 cm.; Cr. Il., 26 cm.; Tr., 29 cm.; D. B. (ext. conj.), 16.5; C. D., 8.5; C. V. (estimated), 7 cm.

The first child, a boy, was born after a labor of 19 hours' duration. Delivery was accomplished by the forceps, the head being so injured by the vigorous compression and traction employed that the infant died shortly after birth. The child was not weighed. The second child, a girl, was delivered alive, spontaneously, after a hard labor of 14 hours. She was not weighed, but was so tiny that she was not expected to live. It is safe to say that she did not weigh *more* than five pounds. The third child, a girl, was delivered by Dr. Howard A. Kelly by Cesarean section. She weighed six pounds, fifteen ounces. The fourth child, a girl, I delivered, after the induction of labor at the thirty-sixth week, by a high application of the forceps. The baby weighed five and one-thirty-second pounds. The B. P. of the fetal head was 7.5 cm.; B. T. 6.5. The labor was extremely difficult, lasting 27½ hours. (Vide *Amer. Journ. of Obstet.*, 1890, p. 418).

I met Dr. Kelly in consultation, and concurred in the opinion that Mrs. X.'s third delivery could be accomplished only by craniotomy or the Cesarean operation. Dr. Harris also had expressed the same opinion. Mrs. X. and her husband unhesitatingly elected the Cesarean operation. Even had her medical advisers recommended craniotomy she would have rejected it. This was largely due to the fact that she is a Roman Catholic; but doubtless it was partly owing to the horrible death of a sister (who also had a deformed pelvis) under embryotomy—a combination, I believe, of version, craniotomy, and decapitation. The sister died from loss of blood. The issue of the case demonstrated the wisdom of the advice given, as delivery would clearly have been impossible without diminishing the head of a baby weighing 6 1/16 pounds. This operation met with much unfavorable criticism, part of which was due to ignorance of the exact facts in the case, and to the prejudices arising from so called conservatism, and part of which was due probably to animosity on the part of the critics. After this lapse of time those who were immediately concerned in the case can look back upon this operation with equanimity. Undoubtedly it had much to do with popularizing the Cesarean operation performed for the relative indication in this country.

Had there been a question as to the available room in this pelvis it would be settled by the fourth labor, in which a premature child, weighing 5 1/32 pounds, was delivered with extreme difficulty. This head was delivered with the bi-temporal diameter engaged, and there was no room to spare. The fit was so tight that I feared it would be impossible to deliver the undiminished head. Yet this fetal diameter measured but 6.5 cm.[1]

The fifth labor is the subject of this report. Mrs. X. consulted me when seven months pregnant. I found that already the head was so large that it could not be pressed into the pelvis. Two weeks later this disproportion was evidently greater, and a careful palpation of the child made at this time led me to believe that it was large rather than small.

[1] For a full consideration of the history of this case, *vide* Amer. Journ. of Obstet., 1890, pp. 237 and 418.

Knowing the deformity of the pelvis, and having a lively recollection of the difficulties encountered at the preceding delivery, I became convinced that it would be wiser to do symphysiotomy at full time than to induce premature labor. I so advised the woman, but asked her to reserve her decision until she had consulted Dr. Parish, who agreed with me in advising symphysiotomy as against the induction of premature labor. So far as I know, this is the first time in which symphysiotomy has been elected over the induction of premature labor.

I opened the symphysis, and delivered by a high application of the forceps, December 5, 1892, at the Kensington Hospital for Women. The cervix being well dilated after a labor of eleven hours, the patient was put in the lithotomy position for operation. The bowels and bladder had been emptied, the lower abdominal, pubic, and pudendal regions cleaned, shaved and disinfected, and the vagina douched. The membranes were now ruptured. It was not considered worth while to try forceps-delivery before proceeding with the operation, because the head was free at the superior strait, and clearly too large to engage.

The operation was commenced by making an incision an inch in length in the median line of the abdomen and terminating at the symphysis pubis. This was carried down to and through the muscular and aponeurotic structures. More room was now afforded by detaching the muscle from the pubic bones by cutting transversely with scissors until the left index finger could be passed behind the pubes. The connective tissue back of the pubes is so loose that the finger encountered no resistance, and was easily passed below the pubic arch. The urethra being now depressed and dragged to one side by a catheter in the hands of an assistant, the Galbiati knife was passed along the finger as a guide, and hooked under the symphysis. This was divided by traction on the knife in an upward and forward direction. Much difficulty was encountered, as apparently the ligamentous structures were not abundant, and the knife became wedged between the bones. The symphysiotomy lasted twenty-six minutes. As there was considerable venous oozing, a sponge was packed behind the symphysis and gauze was laid over the wound.

The forceps was now applied, and the baby, a boy, was delivered after an extremely difficult forceps-labor, lasting thirty-seven minutes. This is explained by the fact that the baby weighed 8⅛ pounds, and that the head measurements were B. P., 9.5 cm.; B. T., 9 cm.; S. O. B. 9.5 cm. After the symphysis was divided the bones separated one-fourth of an inch. After vigorous traction with the Hodge forceps they separated two inches, and the head became well engaged. The Tarnier forceps was now applied, when the head descended into the cavity of the pelvis, and a separation of 2½ inches was obtained. Two assistants now supported the pelvis by pressing on the trochanter upon either side, and drawing upon the ilium of the opposite side. It was interesting to observe that the labor followed the mechanism of the flat pelvis. The head descended semi-flexed, with the occiput to the right ilium and the sinciput to the left ilium, until it began to distend the pelvic floor, when flexion and internal rotation took place. The child was delivered asphyxiated, and required careful attention for ten minutes before it was resuscitated. The use of suspension, head downward, dipping in warm and sprinkling with cold water finally brought it around. The placenta was now delivered, and the vagina and the uterus were douched with sublimate solution, 1 : 2000. The sponge was removed from the operation-wound and the hemorrhage found to be controlled. Several silkworm-gut sutures were passed through the skin and muscle in each lip of the wound, which came nicely together. In the meantime the pelvic bones were pressed together by the assistants. A dressing of aristol and gauze was applied over the wound, over this rubber adhesive plaster, and finally a stout binder coming well below the trochanters. The legs also were tied together for some days. The patient was put to bed without shock.

In performing the operation I had the advantage of the counsel of Drs. Harris and Parish, and Drs. Boyd and Parish kindly took charge of the baby. The operation was witnessed by a number of physicians, among others the venerable Dr. J. G. Allen.

The after-history was absolutely uneventful—a normal puerperium. Tender and abraded nipples interfered with the baby's nursing, which prevented him from thriving for a time; but at the present writing he is fat and well. The extreme asphyxia present at birth probably influenced his nutrition for some weeks.

It was interesting to observe the entire absence of pain in the divided symphysis. I had expected considerable pain from the stretching of tissues, especially below the pubic arch; but the patient expressed herself as being perfectly comfortable.

The after-management of the case was somewhat troublesome, owing to the necessity of using a wide binder to preserve immobility of the pelvic bones. The vulva was washed twice daily with sublimate solution, and well dusted with boric acid. The vagina was douched on alternate days, more especially to assist in the rather troublesome task of keeping the parts clean. This was troublesome, because it was thought best to keep the legs together.

As a matter of convenience, I used two binders. The one next the skin was of two thicknesses of heavy muslin, made with "three tails." The outer one was of canvas. The bandages were secured with safety-pins, and finally when the muslin bandage was dispensed with, straps and buckles were attached to the canvas bandage.

In cleaning the patient the outer binder was unfastened, and also the *lower* tail of the muslin binder. The legs were then separated just enough to permit cleansing the vulva. About every third day it became necessary to apply a clean muslin binder. The patient was rolled on her side, the legs being in apposition, and the pelvis supported, when the soiled binder was removed, and the opportunity embraced to wash the region of the buttocks. A clean binder was then placed in position, the pelvis well supported, and the patient rolled on her back,

when the two binders were fastened. In this way it was possible to keep the patient clean, and at the same time keep the pelvis immobile.

Union of the joint was apparently complete in two weeks. The sutures were removed in six days. Wishing to run no risks of poor union, the patient was kept in bed four weeks, then sent home, and confined to bed for another week. Shortly afterward she was doing the housework for a family of six.

2134 HANCOCK STREET.

In the discussion following the reading of the paper Dr. R. P. HARRIS said: Dr. Noble's patient came under my observation May, 1888, when I saw her in consultation with Dr. H. A. Kelly at her own house, and recommended that she should go to the Kensington Hospital for Women, and there be delivered by the Cesarean operation, which was performed a few days later. When she was pregnant for the fifth time I had become convinced of the value of symphysiotomy, and thought it adapted to her case, because of the form and size of her pelvis, and recommended that it should be selected as a preparation for delivery.

Unfortunately for the facility of its extraction, the fetus proved to be a male, and much larger than any of her former children, so that it made a very narrow escape for its life, being deeply cyanosed and difficult of resuscitation. It, however, thrived well during its mother's recovery, which was free from any pelvic pain or uneasiness. No convalescence after parturition could have been more devoid of symptoms indicative of the enlargement to which her pelvis had been subjected; and when I examined her on the twenty-second day I found pubic union firm and solid.

Dr. Noble's case is one of the most interesting on record, because of its historic character, as symphysiotomy was brought into contrast with the improved Cesarean section and with delivery under induced labor in the same subject, and all with entire success to mother and child. I know of no parallel case in my obstetric readings, and of no evidence in contrast that is more to the credit of the recently introduced method of delivery.

Under an improved technique and proper antiseptic precautions, the operation of Sigault has been robbed of all traumatic dangers, and would appear to be devoid of any risk, when regarded from a surgical aspect. Deaths have taken place since the operation was perfected by Prof. Morisani, and no doubt will continue to take place, when women are operated upon *in extremis*; just as deaths follow after delivery by the forceps or in cases in which craniotomy has been performed. What we contend is that the prior condition of a parturient woman is not rendered the more likely to prove fatal by reason of the section and opening of her symphysis to aid delivery.

During the past seven years, four women out of seventy have died, in whose cases delivery was accomplished with the aid of symphysiotomy: one in Naples in 1890; one each in Helsingfors, Russia, and in Paris, in 1892, and one in the United States this year. The Neapolitan woman was in labor for several days when taken to hospital; the shoulder presented and the cord prolapsed; delivery was accomplished by version, and death took place in twelve days from metro-peritonitis. The Helsingfors patient died of heart-disease and other organic complications on the second day. She was forty years old, and in her ninth pregnancy. The Paris case had been in labor three days with her fourth child; the forceps had been applied three times at her own home, and four times in hospital; one of the last, antero-posteriorly. She died the day after delivery, and a small perforating laceration was found leading from the uterine cavity into Douglas's cul-de-sac. The fourth death was in a woman almost moribund, having a pulse of 150. The children were lost, except in the cardiac case and the fourth that died. Certainly death could not be ascribed to symphysiotomy in any of these cases.

Since September 29, 1892, this operation has been performed ten times in the United States and once in Canada, saving ten women and eight children. One child died in twenty-four hours, from the effect of long-continued pressure upon its head in the lower pelvis, and one in three days, from meningeal hemorrhage: the third has not been reported.

The American operations have been performed, in chronological order, by Prof. Charles Jewett, of Brooklyn; Prof. Barton Cooke Hirst, of Philadelphia; Prof. Anna E. Broomall, of Philadelphia; Prof. Edwin J. Michael, of Baltimore; Dr. Charles P. Noble, of Philadelphia; Dr. J. A. Springle, of Montreal; Dr. Harry McKennan, of Paris, Illinois; Prof. Henry J. Garrigues, of New York; Dr. John Milton Duff, of Pittsburg; Prof. William T. Lusk, and Prof. Henry C. Coe, of New York. In Dr. McKennan's operation, not having a sufficiently strong bistoury, the symphysis was divided by means of a narrow metacarpal saw, guarded by the index finger.

We may arrange the history of symphysiotomy into three periods, viz.: 1777 to 1858; 1866 to 1886, and 1886 onward. In the first period there were over 100 operations; in the second there were 73; and in the third, as far as heard of, there have been 70, of which 36 were in the year 1892, divided as follows: In France, 13; in the United States, 7; Italy, 6; Germany, 5; Russia, 2; Canada, 1; Ireland, 1, and Austria, 1. As Italy had 12 in 1891, it is probable that there were as many as 40 in 1892, as against 12 in 1891.

Some men cannot comprehend my statistics, and are led to believe that *some* of the unfavorable cases must have been hidden away from those who aided me in their collection, in order that the improvement in results should appear so remarkable. We have only to state that a large proportion of the reports were copied from hospital records, and that many other statements came through correspondence. An examination into the diminished mortality of ovariotomy, the Cesarean section and abdominal hysterectomy will show what marvellous changes have been effected within a few years, in the reduction of the death-rate, under antiseptic management.

It was at one time thought that a Porro-Cesarean section, with the stump treated intra-peritoneally, was almost equivalent to a sentence of death, because only one woman was saved out of the first eleven, and yet 25 operations in order, covering the years 1888, 1889, 1890, 1891, proved fatal to only three women. This week brought me a letter from Prof. Leopold, of Dresden, stating that he had performed the Porro operation

eight times without the death of a mother, and that 42 improved Cesarean sections in the Frauenklinik had cost the lives of but four women.

The results of obstetric surgery in the hands of very skilful men are certainly trying to the faith of the casual observer, but they are none the less worthy of credit. Dr. Hubert Riedinger, of Brünn, Austria, was an early operator after the Porro method, having commenced in 1878; and his records show that he has performed 15 sections, saving all of the women and losing but one child.

The late Karl Braun (13), the late August Breisky (8), and Drs. Riedinger (15), and Leopold (8), had collectively 44 Porro operations, and lost but 3 women and 8 children. Such records show the possibility of the operation, but a general hospital report, as of the Maternities of Leipzig, Dresden, and Vienna, is of much more value in the estimation of risks.

If puerperal celio-hysterotomy and celio-hysterectomy have been so largely reduced in their rates of mortality, why should it be regarded as almost incredible that the operation of symphysiotomy, upon women in a *proper condition*, should have no mortality? If what was once regarded as "the murderous operation of *bi-pubiotomy*" has been recently revived in Paris, under Prof. Adolphe Pinard, with the saving of both mother and child, why should we fear the traumatic results of a simple symphysiotomy? In Pinard's case there was a true conjugate of 8.5 c.m., but one sacro-iliac symphysis was ankylosed, and the pelvis was oblique, hence the change of method. This operation originated with Prof. Galbiati, of Naples, who performed it on March 30, 1832, upon a dwarf three and a half feet high, having a one-inch conjugate; the child was dead, the woman died in four days of gangrene of the genitalia and vagina. Ten years later, Dr. Ippolito repeated the operation in Naples, with the same result. Prof. Pinard evidently thought that this operation originated with Dr. Farabeuf, of Paris, who proposed it to him, and he recommended that it be called by his name instead of *ischio-pubiotomy*, by which he reported it before the French Academy of Medicine, on January 10, 1893.

DR. BARTON COOKE HIRST said: Without doubt this operation has now become firmly fixed among justifiable obstetric procedures. There have already been ten operations in this country, and I shall probably add another to-morrow. I have only one remark to make to-night in regard to this matter. After my own operation, which I have already reported, I had a conversation with the President, and received from him a very original and brilliant suggestion. Dr. Mitchell asked me if there were not some way of permanently enlarging the pelvis in the operation of symphysiotomy. It seemed to him that by the insertion of ivory pegs, or by other means, the widening of the pelvis could be maintained. This is a brilliant idea, and I had hoped to have had before now the opportunity of trying it upon animals. The proposition is very interesting and deserves careful consideration. The enlargement of the pelvis in symphysiotomy is considerable. A recent German experimenter has examined, post-mortem, the pelves of three or four women within a few days after delivery, and has found that with a separation of the symphysis to seven centimeters, symphysiotomy gave an increase of three centimeters in the oblique and transverse diameters, and of over one centimeter in the antero-posterior diameter. This enlarges the capacity of the pelvis materially. It would be a brilliant achievement if this could be made permanent by the operation, and if by medical skill we could transform the previous anatomic condition of the patient. It seems almost like sacrilege to think of it. It reminds one of adding a cubit to one's stature, but it seems possible, and I hope soon to have an opportunity of testing Dr. Mitchell's suggestion upon pregnant animals.

PROMINENT SYMPTOMS OF HYPERPHORIA, AS ILLUSTRATED BY THIRTEEN SUCCESSIVE CASES.[1]

BY HOWARD F. HANSELL, M.D.,
LECTURER ON OPHTHALMOLOGY, JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

IN this analysis of symptoms only those cases positively traceable to hyperphoria are included, as demonstrated by their relief or cure, following the correction of the muscular anomaly. Other causes, such as errors of refraction, constitutional diseases, and uterine affections, were excluded.

CASES.

No.	Age.	Occupation.
1. Miss F.,	18	School-girl.
2. Mr. F., married,	49	Stock-broker.
3. Mrs. S., "	48	Housekeeper.
4. A. van S., single,	19	Farm-hand.
5. Mr. R., married,	31	Merchant.
6. Mrs. McP., "	35	Housekeeper.
7. Mr. K., "	36	Merchant.
8. Mr. M., "	36	Preacher.
9. Mr. B., "	55	Superintendent R. R.
10. Miss M.,	28	School-teacher.
11. Mr. P., married,	43	Lawyer.
12. Miss P.,	16	School-girl.
13. Capt. M., married,	42	Army officer.

In two cases the patients complained of their eyes only.

No. 7, a strong, healthy man, free from nervousness of every kind, had pain in the near use of his eyes, so that he was altogether debarred from reading. A correction of a low degree of hyperphoria, worn for several months, was of no service. He was relieved by a tenotomy.

No. 3, a small, delicate woman, complained of constant lachrymation. This had been treated unavailingly for two years by the usual methods. A correction of her hyperphoria and astigmatism had been worn for the same length of time. No tears or mucus were retained in the lachrymal sacs, and both nasal ducts were permeable to large sounds. No nasal obstruction could be determined. The condition was favorably modified by two tenotomies.

---

[1] Read before the American Ophthalmological Society, July 1892.

Photophobia in moderate degree was present in five cases, Nos. 2, 5, 8, 10, and 11. Exposure to the lights of a theater, combined with the effort of seeing the performance, was followed by pain in the eyes and head. No. 11 suffered intensely for from twelve to eighteen hours after each visit, and was obliged to relinquish that form of amusement. Partial or complete relief was obtained by one or more tenotomies. Pain in the eyeballs, either constant or induced by reading, was a prominent symptom in all of the cases. It presented, however, no points of difference from that due to errors of refraction.

REFLEX SYMPTOMS.—Six cases, Nos. 1, 2, 4, 5, 10, and 11, complained chiefly of headache.

Of these six cases, Nos. 1, 2, 4, and 10 may be classed together. Their headache was a constant dull pain, aggravated by any attempt to use the eyes, by travelling, by bright lights, and by similar circumstances. The pain in Nos. 5 and 11 was of a different character. It was sharp, lancinating, intense, commencing in the eyes and spreading to the head, and was at times attended by nausea and vomiting; it occurred twice or thrice weekly, increasing in severity as the day advanced, and was relieved by a night's rest, or quiet and opiates.

Case 11 demands a special word. His headaches began during his college life, twenty-five years ago, and have continued, varying in intensity and frequency according to his environment and the demands upon his eyes. A correction of myopia and astigmatism had no other effect than to improve his vision. Resumption of business, after a year's absence from home in search of health, was speedily followed by a return to his former condition. A tenotomy for hyperphoria, 2°, has given him entire relief. Six months have passed, and he has suffered but once, a few days after the operation. The history of No. 5 was similar, but extended over a shorter period. His headaches recurred three times weekly, necessitating on those days the abandonment of all work. At at the time of my examination he was wearing a perfect correction for a low degree of mixed astigmatism. Prisms for the correction of hyperphoria, 3°, gave immediate relief, with no relapse in three months.

Six cases, Nos. 2, 6, 8, 9, 10, and 11, suffered with vertigo and dizziness, induced by reading, riding in a carriage or railroad train, or by watching rapidly-moving objects, by bright sunlight or artificial light, or by gazing for a protracted time on objects in close proximity.

Two cases, Nos. 6 and 8, were subjects of violent dyspepsia. Digestion was slow, painful, and incomplete, unless the patients sat quietly, and with closed lids.

In four cases, Nos. 2, 5, 6, and 8, the most conspicuous symptoms were excessive nervousness, irritability of temper, and at times mental confusion, associated with headache and inability to use the eyes without discomfort. Attention had not been directed to the eyes as a possible cause of the trouble until after months or years of unavailing treatment directed to other organs. No. 8 became unfitted, through "nervous prostration," to perform the duties of his profession as a preacher. Study was absolutely impossible; writing a few minutes by artificial light gave him a sleepless night; in conversation his ideas were obscured and thoughts confused by a painful consciousness of self; his temper became irritable; his equanimity was disturbed by trivial incidents of home-life that formerly were unnoticed; he became unsocial, despondent, and fearful of himself. Two tenotomies, separated by an interval of two months, have brought about marked improvement in the mental symptoms, enabled him to again find pleasure in his books, and to partly resume preaching. No. 6 had been under treatment for various affections, including uterine disease, for several years, but at the time she came under my observation was free from physical ailment, and had concluded, as a last resource, upon the advice of her family physician, to consult an ophthalmic surgeon. She was excessively nervous and restless, and could with difficulty remain quiet a few minutes. Indeed, while undergoing examination for refraction, violent twitching of the muscles of the face, arms, and hands developed. Her nervous history included chorea, irritability of temper, temporary loss of memory, or a forgetfulness of the commonest things in every-day life. She was disturbed by trifles, her self-control was lost at times, and only regained by seeking seclusion in a dark room, when her thoughts immediately became logical. I found hyperphoria in emmetropia. A rational explanation of her symptoms should be sought in the exaggeration of the susceptibility of an exceedingly nervous organization, induced by long-continued suffering from uterine and other complications, and maintained, after these causes were removed, by eye-strain. I am warranted in this assumption by the change effected by correcting prisms. After wearing them a few minutes her restlessness subsided. After a few days she reported decided improvement. Withdrawal of the prisms was followed by a renewal of the symptoms. A tenotomy was performed, but I cannot at this time state the final result.

My experience with prisms and tenotomies for the cure of local and reflex symptoms referable to the eyes, but not to an error of refraction, encourages me to seek for their cause in muscular anomalies.

254 S. SIXTEENTH STREET.

ORIGINAL LECTURE.

DESTRUCTION OF THE GASSERIAN GANGLION FOR TRIGEMINAL NEURALGIA; WITH A REPORT OF TWO CASES.

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF BUFFALO, N. Y.

[Reported by A. L. BENEDICT, A.M., M.D.]

CASE I.—This patient, a man aged 53, thin, worn-out, and haggard, shows in every lineament the evidence of intense and prolonged suffering. His history is one of chronic, intractable, spasmodic facial neuralgia of the right side, extending over a period of five years. As is usual in such cases, we cannot elicit any facts from the antecedent history which will account for the neuralgia. In certain cases we may ascribe neuralgia to diseased teeth, to tumors pressing on some part of the fifth nerve, or to manifest reflex causes, but, as a rule, we must look more deeply for an explanation. In this instance, the pain was at first referred to the branches of the second (superior maxillary) division of the fifth nerve; later it involved the first (ophthalmic) division; only rarely has there been pain shooting down the third (inferior maxillary) division. Whether this be a case of true neuralgia or one of neuritis, whether there be some little bony outgrowth, causing pressure on one of the branches of the nerve as it passes from the cranium, and affecting reflexly the other branches, or whether there be no tangible cause for the trouble, the demand for relief is equally urgent. The patient has been sent to me for that relief because life is not worth living to one in his condition and because he has demonstrated his opinion to that effect by more than one attempt at suicide. Although he has been taking morphine in grain-doses, his sufferings have continued and have made him irrational, so that his family have to watch him constantly to keep him from self-destruction. Under these circumstances it is proper to proceed to almost any extreme in order to afford relief, and even if death should occur as the result of surgical interference, the surgeon would not be blamable.

Before describing the operation, let me outline the anatomy of the trifacial nerve. Proceeding from the medulla, it passes beneath the base of the brain to the petrous portion of the temporal bone, over which it passes, crossing the lateral sinus, and enlarging to form the Gasserian ganglion, which is lodged in a depression on the upper surface of this petrous portion. Up to the Gasserian ganglion the nerve is soft and friable and unlike ordinary nerve-tissue as we meet with it surgically; in fact, it more closely resembles the white matter of the brain. After leaving the Gasserian ganglion it becomes firmer and more fibrous, and branches into three strong cords. The first division passes out through the anterior lacerated foramen, to supply the structures of the orbit with common sensation; its largest branch going to the forehead through the supra-orbital foramen or notch, and also supplying the scalp. The second branch makes its exit through the foramen rotundum in the great wing of the sphenoid, whence it passes into the spheno-maxillary fossa. Here it connects with Meckel's ganglion and thence it sends branches in various directions. Its main trunk penetrates the upper jaw and a portion emerges from the infra-orbital foramen. The third division of the trigeminal nerve receives a motor root after leaving the Gasserian ganglion. It passes out through the foramen ovale a little below and behind the foramen rotundum and divides into the inferior dental and gustatory nerves after giving off muscular branches to the pterygoids, the masseter, and the temporal muscles. Although these branches may be accidentally divided, I shall give little attention to them to-day, for the diffusion of the pain points to its source in the Gasserian ganglion and an operation on one of the branches of the nerve would not be radical.

Several routes have been demonstrated by which the Gasserian ganglion can be reached. The first to destroy the ganglion was Professor Rose, of London, who did so at the instigation of a patient willing to risk anything for the sake of relief from the pain which he suffered. He removed the upper jaw—the locality in which most of the pain was felt, trephined through the base of the skull and attacked the ganglion. Professor Horsley has trephined through the skull laterally, and reached the ganglion from above, but the patient did not survive the shock of the operation.

The originator of the operation which I purpose performing to-day is my friend and former teacher, Dr. Andrews, of Chicago. He has reported two operations of his own of this kind; since then I have performed the operation once, and a surgeon of New York City has performed it once. Altogether the ganglion has been attacked about eight times before this.

I shall expose the zygoma by an H-shaped incision, saw it in two places, and turn down the detached portion with the masseter muscle. In order to secure the zygoma in place again, it will be necessary to drill each side of each line of section, and the drill-holes can be made more conveniently while the bone is firm than after dividing it. The turning down of the zygoma exposes the coronoid process of the inferior maxilla with the insertion of the temporal muscle. This process is also to be drilled twice and sawed across. Then, with the mouth widely opened, there is a space, not liberal but yet sufficient to allow one to attack the base of the skull under the Gasserian ganglion. There is a quantity of fat and connective tissue to be cleaned away from this fossa and the internal maxillary artery will probably require ligation. Then we get to the pterygoid plate, from which the external pterygoid muscle takes its origin. This muscle must be cleared away, perhaps by detaching it from the bone, perhaps by dividing it. Although it is a useful muscle, it is not essential and we may, if necessary, remove it entirely. Following the external pterygoid plate as a guide, we reach the foramen ovale, through which emerges the third division of the fifth nerve. The Gasserian ganglion lies between two layers of the dura mater, which splits to enfold it. The lower layer is very thin; the upper layer is strong and protects the superjacent structures. It is not possible to exsect the ganglion as one might take out a tumor, for it is concealed from view and is soft and friable. I expect to tear it with a blunt hook and knife and thus to dispose of it as far as its function is concerned. If you recall the proximity of the middle meningeal and internal carotid arteries to the lateral sinus, you can appreciate

the difficulty of the operation. At my operation last summer, two hours and a quarter were consumed, but the greater part of the time was spent in checking hemorrhage from numerous small vessels in the sphenomaxillary fossa. I have decided to obviate this difficulty by tying the common carotid artery at the point of election, the guide being the anterior border of the sterno-cleido-mastoid muscle. There is usually found a little vein connecting the facial with the internal jugular, or sometimes the external jugular lies across the line of incision. This, however, is a matter of trifling moment. After dividing the platysma myoides and removing some connective tissue, I get down upon the carotid sheath. The descendens noni nerve lies upon this, and I turn it aside before dividing the sheath. It would cause no very serious trouble if one should fail to recognize the descendens noni and divide it. By means of a moderate-sized catgut thread I draw a heavy catgut ligature around the artery from the inner side. After tying the artery, I close the outer wound with a continuous buried suture, which has the advantage over the interrupted suture of being more quickly made and of leaving no cross-marks on the scar. An antiseptic gauze dressing is applied, and by the expenditure of a few minutes' time I hope to avoid the hour's delay which I experienced at the former operation. No one else, so far as I know, has seen fit to ligate the carotid before the main operation.

Now, as I make the H-shaped incision over the zygoma, you see what anastomosis will do, for in spite of tying the common carotid, there is considerable hemorrhage. I next scrape back the periosteum to expose a track for the saw, make the four drill-holes and saw and chisel through the bone.

The patient is pretty feeble, and if his strength shows signs of failing, I shall abandon the proposed operation and content myself with extirpating Meckel's ganglion, thereby hoping to do away with most of the pain, which is referred mainly to the second division of the nerve.

The balance of the operation was completed without special incident. The base of the skull was easily exposed, and the benefit of tying the carotid became very apparent, as very little delay was caused by hemorrhage, either active or passive. The trephine driven by the De Vilbis engine was used for a part of the work of exposing the ganglion, and small chisels for the rest. The dura was then opened, the ganglion broken up with a blunt hook, the second branch pulled out from the foramen rotundum, and, together with Meckel's ganglion, excised. The wound was then closed without drainage. A small incision was next made over the supra-orbital notch and the nerve found and pulled out from its channel till it broke; the external portion was removed.

The patient rallied well from shock and the wound healed rapidly, there being only a little superficial late suppuration. Pain was relieved at once, and the patient returned to his home, in Fairport, N. Y., in about twelve days.

CASE II.—The patient was an anemic woman of fifty-four. The right lateral region of the head had been previously shaved, and the head was enveloped in an antiseptic dressing. Chloroform was administered. After the patient was placed on the operating-table the forehead, eyebrow and side of the face were shaved in order to remove fine hairs and sebaceous matter. The brow was shaved in anticipation of the possible necessity of operating on the supra-orbital branch of the ophthalmic nerve.

The first incision, 5 cm. long, was made at 11.35 A.M., directly downward from the external angle of the orbit. The second incision was parallel to the first, ½ cm. in front of the tragus. These incisions were connected by a horizontal incision over the zygoma. The periosteal elevator was used to mark the lines of division of the zygoma. The telescope drill was applied to either side of each line, the zygoma separated by saw and forceps at the outer line, by saw and chisel at the inner line. One of the inner perforations was crossed by the line of section of the bone, and another perforation was made. Spiculæ of bone were removed by the cutting-forceps. Fat was removed from the zygomatic fossa and three small bleeding vessels were tied. The elevator was slipped under the coronoid process of the inferior maxilla, and the bone drilled twice for subsequent wiring.

At 11.49 the coronoid process was severed by cutting-forceps and reflected upward. There ensued much venous oozing, that prevented the finding of the internal maxillary artery. The wound was stuffed with gauze for two or three minutes. An assistant then held the mouth open, the absence of teeth rendering the gag superfluous. A 5 per cent. antipyrin-spray was used to check hemorrhage. At 12.04 the internal maxillary artery was found to have been accidentally divided; one end was pulsating but closed by a clot, the other end was bleeding. Both extremities were tied with fine catgut. The artery was very small.

Dr. Park stated that he could now feel the foramen ovale, but could not feel the nerve. Small sponges in hemostats were used to clear the bone of fat, cellular tissue and blood. At 12.15, the antipyrin-spray was again used. A trephine about ½ cm. in diameter was applied to the sphenoid bone, the motive power being a surgical engine turned by hand. After penetrating the bone and removing the fragments, there was some hemorrhage from the small meningeal artery, which is easily torn in such operations. The trephine-opening was connected with the foramen ovale by means of a small chisel. Delay followed on account of hemorrhage. At 12.45, the dura matter, pulsating, bulging under the Gasserian ganglion, was exposed in an oval area about 1 cm. by ½ cm. At 12.56, the outer layer of the dura, apparently double, was divided and the ganglion exposed. On attempting to cut it there was considerable hemorrhage. A blunt wire applicator bent into a hook was used to tear the ganglion. The cavity was stuffed with gauze to control hemorrhage. The bony margins were chipped away with a chisel. Transmitted impulse was very marked. The antipyrin-spray was again used. At 1.10 the fragments of the ganglion were torn away with a small hook, the second branch of the nerve was pulled out of its channel and a portion, including Meckel's ganglion, was cut away. The supra-orbital nerve was pulled through the notch and excised. The coronoid process was restored to its place with silver wire passed through the drill-holes. The zygoma was similarly secured. The wound was closed with catgut over catgut drainage and an antiseptic dressing was applied.

CLINICAL MEMORANDA.

SEVERE FRACTURE OF THE VERTEX, WITH REPLACEMENT OF A LARGE FRAGMENT OF BONE.

BY HOMER R. PAGE, A.M., M.D.,
PROFESSOR OF OBSTETRICS, IOWA COLLEGE OF PHYSICIANS AND SURGEONS, DES MOINES,
AND
WOODS HUTCHINSON, A.M., M.D.,
PROFESSOR OF ANATOMY, STATE UNIVERSITY OF IOWA.

OUR excuse for presenting this case is principally the unusual size of the fragment removed and the promptness with which it reunited with the periosteum. So far as our research has extended, it appears to be the largest piece of bone on record completely torn from its attachments and successfully replaced. The extent and distribution of the pareses are also of some interest.

At about noon of June 17, 1891, we were summoned to an "accident case" at a coal-mine about three miles east of Des Moines. On our arrival at the place we found the "pit-boss," a Scandinavian of about thirty-five years of age and a magnificent specimen of physical development, lying upon a rickety cot in the shanty at the mouth of the pit, with the top of his head literally crushed in.

We were told that about an hour before he had gone down into the mine on a tour of inspection, and sending the cage-tender to make some repairs, had taken charge of the shaft-base himself. While reaching forward into the cage to get hold of an empty truck, he was struck on the head and rendered senseless by a large piece of falling coal, which had in some way been dislodged from a loaded car at the top of the shaft, 120 feet above. One of the men heard the whiz of the falling coal, followed by a heavy thud, and running to the spot found the boss stretched across the empty truck, with a frightful gash across the top of his head.

The wounded man was lying quietly on his cot, in a curiously apathetic condition, his eyes wide open and glancing with apparent recognition at everybody about him, without a sign or trace of pain, or even uneasiness in his position or expression, and completely aphasic. He seemed to hear perfectly, turning eyes and face promptly toward the speaker; his pupils were normal in size and activity; breathing was easy and regular; the pulse was 70, full and elastic; face and extremities were pale and cool. The man could move his right hand and arm fairly, but slowly, and opened his mouth and protruded his tongue with perfect steadiness when directed to do so, but otherwise seemed completely helpless. When his wound was touched the muscles of his face moved a little, but with no sign of pain. In short, there was loss of speech and of sensibility and motility in the greater part of his body, though in other respects the condition of the man appeared normal. He swallowed readily the liquids given him, and the sphincters were unaffected.

On examination, a gash was found extending from about the right parietal eminence to about an inch above the left mastoid process, at the bottom of which could be felt and seen a long, jagged, depressed fracture. Any operation in that tumble-down shanty, with no furniture save a broken cot and rusty stove, being out of the question, a temporary dressing was hastily applied and the man was lifted into an ambulance, which had followed us from the city, and conveyed to his home, some three miles distant. Just as the dressing was being laid in place, the patient lifted his right hand to his head, and withdrawing it covered with blood, held it before his face and gazed at it curiously for several seconds, seeming to recognize the condition of affairs, but without giving the slightest sign of fear or uneasiness. He stood the trip splendidly, without any appearance of discomfort except a slight contraction of the facial muscles as he was being lifted into the ambulance. Everything was in readiness by the time he arrived—a large dining-table covered with blankets and an oil-cloth, several gallons of boiled water, and the instruments arranged in boiled water.

On careful examination a large segment of the calvarium, about 4½ by 2½ inches, of a triangular shape, was found depressed completely below the surface of the inner table: its longest (posterior) border ran diagonally across the vertex, from 5½ inches directly above the right to 4 inches above and ½ inch behind the left auditory meatus, while its obtuse angle lay directed forward at a point 4½ inches above the middle of the left superciliary ridge. The surface of the depressed portion and of the skull for from ½ to 1 inch all around was completely stripped of periosteum, which, with the other tissue of the scalp, was turned forward in a huge matted flap, swollen by extravasated blood to a thickness of fully ⅔ of an inch, and with its edges and under surface literally asphalted with coal-dust.

A little extension of the gash at its edges with a scalpel allowed this to be turned forward completely out of the field of operation, and the cavity having been thoroughly cleansed and flushed with very hot (110°–120°) boiled water, the head was shaved and a couple of buttons removed with a half-inch trephine, one in front about an inch from the right extremity of the fracture, and the other behind and about half an inch from the left extremity. The patient winced a little at the gritting of the trephine and groaned slightly, but otherwise gave no sign of pain during the operation, so that no anesthetic was required.

An elevator was introduced, first through one hole and then through the other, but the fragment was positively overlapped by the edges of the skull, like a keystone by the sides of an arch, and it was only by each taking an elevator and literally prying the edges backward and the fragment upward, that it could be made to budge. When it did become loose, it was with such suddenness that the piece went flying not only clear of the wound, but almost clear of the table.

Only a few shattered fragments of bone were left, at about the middle of the posterior border of the gap. The large fragment was promptly placed in a bowl of blood and hot water, and the operation proceeded with. After the shattered pieces were removed, and the surface of the inner table all around had been explored for splinters with the finger, the dura was found unbroken except at a point near the left acute angle of the gap, where a small spicule had been driven through it to the depth of about half an inch.

There was a good deal of bulging of the membranes,

and subdural hemorrhage was feared; in fact, there was quite a free flow of blood through the puncture made by the spicule; but it appeared to be principally venous, and we succeeded in checking it entirely and moderating the bulging by prolonged affusion with hot (boiled) water poured out of a pitcher into the wound. This done, the fragment was taken out of the bowl of "culture-fluid," and after much manipulation and the application of considerable lateral traction was reinserted into the gap, the sides of which held it as if in a vise. It fitted as accurately as a segment of a Chinese puzzle, with the exception of the small space on the posterior border occupied by the shattered fragments. Neither these nor the trephine-buttons were replaced, with a view to leaving a ltttle room for relief of any tension that might occur.

The wound was then freely flushed with a fifteen-volume solution of hydrogen dioxid, and the edges of the flap were thoroughly cleansed with the same solution and stitched together as accurately as possible, although perfect coaptation seemed almost out of the question on account of the swollen condition of the tissues of the scalp. No opening was left for drainage, and a simple pad of moist carbolized gauze dusted with iodoform was applied.

Almost immediately upon the elevation of the fragment the patient lifted his head, inquired where he was, and answered questions slowly but rationally; he also winced when the hot water was poured into the wound, and when the sutures were introduced; but, when asked if he felt any pain, replied: "None to speak of."

The operation occupied about an hour and a half, and at its close the patient was in a condition of shock, though not at all profoundly so. A subcutaneous injection of strychnine, with morphine and atropine, was given; hot bricks and bottles were packed around him in bed; and he soon rallied. Four hours later he was perfectly conscious and resting quietly, with a weak but otherwise natural pulse. On the next morning his temperature was 99°, his pulse 72.

When the dressing was removed the swelling of the scalp was found greatly diminished, the edges of the wound glued together, and not a drop of pus anywhere. There had been a free leakage of reddish serum into the dressing. The parts were flooded with hydrogen dioxid, and the dressing was reapplied. On the next morning the temperature was 99°, the pulse 75; the swelling of the scalp was two-thirds gone and the wound united by first intention along its whole course, with the exception of the lowest angle, where there was a slight opening, through which we pressed out nearly half an ounce of reddish fluid, resembling broken-down blood-clot.

On the following day (June 20th) the temperature stood at 98.5°, where it remained all through the remainder of the case, and a smaller amount of reddish fluid was passed out through the opening at the lower angle. Some ecchymosis developed at the left temple, but gave no trouble, and gradually faded away in a few days. The patient then took fluid food freely, stating that he felt "only a little soreness of the scalp"; he rested quietly during the day, but at night was restless and inclined to be delirious, twisting about in the bed, clutching at the bandages, and attempting to scratch the top of his head. From this time forward the surgical course of the case was an uneventful progress toward recovery. There was absolutely no formation of pus, the only discharge being a slight amount of clear, yellowish fluid of about the consistency and appearance of honey.

About two weeks after the accident the probe detected a patch of bare bone, about half an inch in diameter, at the point of greatest splintering, and a number of tiny osseous spiculæ were discharged at intervals, up to as late as eight months afterward; but with this exception the whole fragment seems to have united with both periosteum and diploë perfectly.

The mental condition of the man was normal throughout, with the exception of the nocturnal delirium spoken of, which on one or two occasions rendered him quite difficult to control, and a decided irritability of temper and suspiciousness of mind on the third and fourth days, especially toward his wife, whom he several times ordered out of the room, saying that she was trying to keep him from getting well. These manifestations, however, soon passed away.

The most interesting features in the case were the pareses, which were strikingly characteristic. Upon recovery from the shock of operation, both legs were found to be completely paralyzed, with the exception of the right hip and thigh, which were only partly so, and could be slowly flexed on the body with a little assistance from the right hand. The left arm was powerless, with the exception of a little feeble movement in the forearm and hand; while the right arm was under good control, with the exception of the deltoid, in consequence of which he was unable to lift it above the level of the shoulder. The muscles of neck, face, jaws, and trunk were apparently unaffected. Speech was somewhat hesitating, but otherwise perfect.

Sensibility was everywhere preserved, although apparently slightly dulled, as the man felt little or no pain when the wound was dressed or touched. The sphincters were unaffected. The pareses remained stationary, or, if changed, were slightly increased for three days, after which gradual improvement set in, which steadily continued to recovery, except in the right leg.

In ten days the man began to move the left leg a little; in a month he could stand alone for a few minutes; in six weeks he was able to scramble into his buggy and drive to the office or to walk about slowly with a couple of sticks.

At present, a year after the accident, the man has perfect control of all of his muscles, excepting those of the right leg and thigh, which still feel "heavy and stiff." The disability is decidedly most marked in the calf and foot, which latter, when lifted, tends to assume the fetal position, with the sole drawn upward and inward. The muscles are firm, well-nourished, and strong; the limb will support his whole weight easily, and if he moves slowly and quietly he can, with the aid of a cane, walk considerable distances with ease; but if he gets excited or attempts to hurry, the leg "goes stiff" at once, and he can hardly move it. There are and have been no sensory disturbances except a well-marked and at times severe tingling and "cramping" while the pareses were first disappearing.

Upon careful measurement, the posterior scar was found to extend diagonally across the vertex from a point three inches above the posterior border of the left

mastoid process to a point just in front of the right parietal eminence. The posterior line of fracture lay half an inch anteriorly to and was one inch shorter at either extremity than this. From the extremities of this, two slightly elevated and roughened lines of united fracture could be distinctly traced, running forward and inward and meeting four and one-half inches directly above the middle of the left superciliary ridge (at the coronal suture, three-quarters of an inch below the bregma), thus making the replaced fragment four and one-half inches in length by two and one-quarter inches in its greatest (antero-posterior) breadth.

The posterior line of fracture—the line of actual impact and of greatest depression—crossed the sagittal suture about one-eighth of an inch behind the upper extremity of the fissure of Rolando according to Thane (seven inches out of thirteen and one-quarter inches), or about one-quarter inch behind, according to Broca (two and one-eighth inches behind bregma), while the area of splintering, in which the spicule penetrated the dura and from which dead bone was subsequently discharged, lay three-quarters of an inch to the left of and half an inch anteriorly to this, thus covering accurately the very center of Horsley's "leg-area." The other pareses have an equally clear origin. While the fragment was depressed, its extremities, of course, reached lower down upon the surface of the brain, low enough upon the left side to press upon the speech-center and produce aphasia, which was promptly relieved by the elevation of the bone, while it completely covered the leg-area and arm-area on both sides, with the exception of that portion of the left arm-area lying anteriorly to the Rolandic fissure (for the right forearm and hand).

The centers that lie highest were most severely affected in regular gradation: the legs were more completely paralyzed than the arms, and were much slower in recovering. The same is true as between the different parts of each limb; in the arms, the fingers and hands were the least affected and quickest to recover; the shoulders most affected and slowest; indeed, I think there is still a little lack of power in the right shoulder, although the patient declares it to be as strong as ever.

In the legs, the hips and thighs were the least affected and first to recover; the ankles and feet, most affected and last to recover; the only marked remaining paresis being that of the right foot and calf.

In view of the shattering of the bone and wounding of the dura in this region, it seems probable that a certain amount of cortical tissue was damaged beyond possibility of repair, and that such control as the patient possesses over the limb is through the functional activity of the corresponding center of the opposite side—a fact that would also account for its "growing stiff" during hurry or excitement, the center being, so to speak, not yet educated up to taking care of both limbs at once under pressure.

Paraldehyde for Spasmodic Asthma.—MACKIE (*British Medical Journal*, No. 1672, p. 65) has reported the employment of half-dram doses of paraldehyde, repeated every half-hour or hour, in the treatment of a number of cases of spasmodic asthma, with uniformly successful results. Spasm was speedily relieved and sleep soon followed. In no case were more than three doses required, and usually one sufficed.

ACHILLODYNIA.[1]

BY AUGUSTUS A. ESHNER, M.D.,
CHIEF CLINICAL ASSISTANT, OUT-PATIENT MEDICAL DEPARTMENT, JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

THE man whose case I herewith detail presented himself at Jefferson Medical College Hospital, in the service of Dr. H. A. Hare (by whose courtesy this report is made), complaining of swelling and soreness in the region of the heels, that had been present for about four weeks. He was twenty-two years old, a car-cleaner by occupation, and stated that he had had a similar attack three and a half years previously that lasted for about fourteen months, and apparently had disappeared spontaneously. The pain appeared after walking, and was relieved by rest, either in the sitting or recumbent posture. The swelling, however, persisted. There had been no traumatism of the parts, and there was no history of rheumatism, and none of gout. The man had been infected with gonorrhea four years previously (that is, half a year preceding the first attack of swelling and pain about the heels). The urethritis had never been entirely cured, remaining at times latent for months, and then breaking out with its former intensity. Within this time, he stated, one of the testicles (perhaps it was the epididymis) had been swollen, and there had been enlargement of one or more glands in the right groin. No history could be obtained of a sore upon the genitals, of cutaneous eruption, of involvement of the mucous membranes, of alopecia or of other manifestation suggestive of secondary syphilis. There was no heart-lesion, and the urine presented no abnormality. There was no history of a similar affection in other members of the family.

On examination a firm swelling was found above the heels, apparently inseparable from the os calcis, and over which passed the tendo Achillis. Manipulation induced pain. Station was steady; the knee-jerks were preserved; the pupils were equal, regular, and responsive to light. I was at a loss to account for the condition, as I had never before seen its counterpart; and in the absence of more definite information I made a tentative diagnosis of syphilis. It was directed that small blisters be applied to the heels on either side of the tendo Achillis, and potassium iodide was prescribed for use internally. The man returned a short time afterward, unimproved.

A few days days after the case had presented itself I came by chance across a note in the *Wiener medicinische Presse*, 1892, No. 2, p. 43, by Professor Albert, of the University of Vienna, in which he reports one of a half, dozen cases that he has encountered in the course of a number of years, characterized by intolerable pain on walking or standing, while no discomfort was suffered in the sitting or recumbent posture. The pain was accurately referred to the insertion of the tendo Achillis, in which situation there was sometimes also a slight prominence, as if the tendon were thickened. As a rule the parts were not unduly sensitive upon pressure. In some cases the bone on either side of the tendinous insertion appeared to be enlarged. The pain was exceedingly rebellious and resisted hot applications, cold applications, counter-irritation with tincture of iodine and

[1] Read before the Philadelphia County Medical Society, February 8, 1893.

inunctions of mercury. Albert was unable to find any reference to the subject in literature. He relates that Raynal and Kirmisson have described a "peri-tendinous cellulitis of the tendo Achillis," which, however, does not agree with the condition under consideration; and he refers to a description by Pitha (Pitha-Billroth's *Handbook of General and Special Surgery*) of a "partial rupture of the tendo Achillis" and a "partial evulsion of the insertion of the tendo Achillis," in which the symptoms recorded agree with those here detailed. The opinion is expressed that the cases attended with swelling of the tendon are described as instances of rupture, while the cases in which enlargement of the bone is present are considered as instances of evulsion. In one case of Albert's the pain was aggravated by exacerbations of a specific urethritis. Kirmisson is also quoted as having noted in one case a connection with an attack of gonorrhea. Albert suggests that the condition may be analogous to a deformity sometimes found in horseback riders, dependent upon a hyperplasia of periosteum and bone at the point of attachment of the great adductor muscle of the thigh.

The name achillodynia is proposed for the affection, and is sufficiently descriptive, without committing one to any view as to its nature, etiology, and pathology. Concerning these we can only speculate. To complete the analogy with the condition found in riders, there should be, as suggested by my friend Dr. J. K. Young, a history of some corresponding muscular strain, such as standing on the toes for a considerable length of time. This was not present in the case here reported. The affection should thus be frequently encountered in professional dancers. The condition does not seem to be an acute inflammation. If the process be at all inflammatory the action is of an exceedingly low grade. The condition may be a neurosis, with trophic changes. There is one other possibility, and that is that, in some cases at least, the condition is a manifestation of an intoxication of gonorrheal origin.

I do not know what importance is to be attached to the condition here considered. Possibly it is less uncommon than would appear. I present the case as a clinical curiosity. It may prove interesting, perhaps instructive to others who may have encountered cases of a similar kind.

The features that seem to me to be of especial interest are the circumscribed character and the symmetry of involvement; the thickening above the heels; the absence of inflammatory symptoms; the presence of the pain only after walking; and the apparent spontaneous subsidence of the first attack.

A RARE OCCUPATION-NEUROSIS.

BY HAROLD N. MOYER, M.D.,
OF CHICAGO.

WRITER'S cramp was the first of the group of occupation-neuroses to be studied. For a short time it stood alone, but soon a number of other allied disorders, peculiar to those who pursue special occupations, were described, and they have all finally been grouped under the general term. It is probable that the occupation muscular atrophies ought to be included in the same general category. While the pathologic changes in these disorders are very diverse, they all have a common etiology in the continued use of special muscles or groups of muscles.

Those occupations that require a continuous and delicate adjustment of the muscles of the hand seem to be most liable to this affection, the disorder being most frequently observed in writers, violinists, pianists, and telegraphers; but examples are not wanting in those occupations requiring extended excursions of the limbs and the use of the larger muscles, such as ballet-dancing, blacksmithing, and the like.

The occupation-neuroses may be naturally classified, according to the predominant symptoms, into spastic, neuralgic, tremulous, and paralytic forms; though it should be remembered that all of these occupation-neuroses bespeak essentially a disturbance in motility. It is probable that in most of them we have an essential neurosis, without structural change, though some form of peripheral neuritis often complicates the disorder.

The following case is unique in some respects, and, following precedent in these cases, might not inaptly be termed the shoe-salesman's disease.

S. C., twenty-six years of age, single, is a salesman in a large retail shoe-store. The family history is good. Though the patient is decidedly nervous, he has never had any serious sickness or injury. Four months ago he noticed a stiffness in both feet, but more marked in the right. He was then in the habit of sitting upon the right heel when engaged in fitting shoes; when in this position the foot was sharply flexed upon the leg, and the leg on the thigh. As he used the right leg the more in this way he changed to the left, when he observed that it in turn was more affected. He then began to use the right leg again, and the latter now gives him the more trouble.

There is very considerable loss of power in the anterior tibial muscles, especially on the right side. The foot on this side cannot be flexed beyond a right angle. On the left side he can do somewhat better, but there is a decided loss of power.

The right great toe is cold and numb. Extending from its tip to about the middle of the dorsum of the foot is a space, about one inch in width, in which the tactile sense and the temperature-sense are greatly impaired. There is, however, no loss of pain-sense in this area. Sensation in the left foot and leg is not impaired. The deep reflexes are symmetrically increased. There is no incoördination or evidence of disturbance in the central nervous system, with the exception of mild neurasthenia. The faradic current gives a contraction over the tibialis anticus with a coil distance of 5 cm. The contraction was alike on both sides. The galvanic gave K. C. C. 7 m.a. on the right side, and A. C. C. 4.5 m.a. On the left side minimum contractions were obtained by K. C. C. 7 m.a., and A. C. C. 7 m.a. The peroneal nerve gave a normal series of reactions.

It will be seen from a consideration of the foregoing symptoms that we have an occupation-neurosis, but one that is apparently dependent upon changes in the muscles or nerve-endings. The electric reactions show only a partial degeneration. The anodal contraction exceeds the kathodal in the right, or most affected, leg, but in the other the kathodal and anodal are equal. The faradic reaction is substantially alike on both sides. It is possible that we might have a pressure-paralysis, but it is difficult to see how pressure could be applied to the nerve

which supplies the anterior tibial muscle in the position in which the man habitually worked. The fact that the disorder affected the opposite side as soon as it was brought into use is against this view. The electric examinations thus far made in the occupation-neuroses are very contradictory, and it is impossible to say whether neuritis can be excluded by this means or not. It is just possible that the case may have some relation to the "paradoxical contraction" of Westphal. Certainly we have in this case a "paradoxical paralysis" in the fact that it occurred in a muscle that was placed in extreme relaxation by the movements which produced and intensified the paralysis.

MEDICAL PROGRESS.

Gastrotomy for the Removal of a Peach-stone from the Esophagus.—FINNEY (*Bulletin of the Johns Hopkins Hospital*, iii, 26, p. 117) has reported the case of a farmer, forty-nine years old, who, while eating a peach, stumbled and fell, and, in the sudden effort to recover himself, swallowed the stone, together with a portion of the peach. There was at once a sense of lodgment of the body about half-way down the esophagus. Immediately after the accident, prolonged and forcible, but unsuccessful attempts at removal had been made. For four days the man was unable to swallow more than half a teaspoonful of water at a time. There was a constant feeling, at times painful, of the presence of a foreign body in the gullet, with a continual inclination to swallow. A small, ivory-tipped probang encountered an impassable obstruction 12.3 inches from the incisor teeth. A sensation of tapping a solid body was perceived. It was impossible to dislodge the obstruction by means of bougies. On the following day the patient was anesthetized, and the probang was found to pass the obstruction, without, however, dislodging it. No better success was had with a horsehair probang and a flexible bougie. Preparation had been made to perform gastrotomy, if the circumstances warranted. An incision, 5¾ inches long, was made, parallel with and three-quarters of an inch below the left costal arch. The stomach was exposed, lifted out, and incised for a distance of two inches. Neither with the hand nor with various instruments tried was it possible to dislodge the foreign body. Finally, a bougie was passed into the esophagus through the stomach, and brought out at the mouth. To the extremity of the bougie was attached a strong silk thread, to this a sponge, and to the sponge another bit of silk. By withdrawing the bougie through the stomach the stone was dislodged, and with the finger hooked out and removed. The various incisions were then closed. The patient had an uneventful convalescence of two weeks. For a few days he was fed by the rectum. Then he was successively given water, crushed ice, milk, and solids. In ten days he was up and out of doors. Two days later he had a slight chill, and the temperature rose to 102.5°. An examination of the blood disclosed the existence of a moderate leukocytosis, but no malarial parasites could be found. In the course of a few days more, dulness on percussion became evident at the base of the left chest. The introduction of an aspirating-needle disclosed the presence of pus, and a diagnosis of mediastinal abscess was made. A portion of the eighth rib was excised, and a large pus-cavity, which appeared to be behind, and to have no communication with the pleural cavity, was evacuated. No bacteria were found in the pus. The patient speedily recovered, and was soon dismissed. He gave a history of always having had some difficulty in deglutition. Six years previously a piece of meat had lodged in the esophagus for thirty hours.

The Relation of the Posterior Root to the Posterior Horn in the Medulla and Cord.—As a result of a careful study, TOOTH (*Journal of Physiology*, December, 1892, p. 773) concludes that the posterior roots are the only points of entrance of sensory or, more broadly, centripetal impressions into the spinal nervous system. In the medulla oblongata the fifth nerve is the great sensory nerve, corresponding to an unknown number of sensory roots. Its so-called ascending root descends in the medulla and cord to the level of the second cervical root, sending fibers all the way to and through the accompanying substantia gelatinosa. The entering posterior root fibers may be divided anatomically into three groups: (1) a mesial group, entering the postero-lateral column, distributed in part to the postero-median column and in part to the base of the horn, to be further distributed to the posterior vesicular column and anterior horns; (2) a middle group, distributed mainly, if not entirely, to the substantia gelatinosa and its plexus; (3) a lateral group, distributed to the border zone. The ascending root of the fifth nerve, in its anatomic relations to the substantia gelatinosa, corresponds to the middle group of a number of posterior roots. At the level of the second cervical root the ascending root and the spinal posterior root are seen together, the former passing into the substantia gelatinosa, the latter round it to the substantia spongiosa. No experimental method of discriminating the various forms of sensory impressions that enter by the groups of fibers named has yet been devised. Certain tracts degenerate after section of the posterior roots, but experimental lesions of these tracts themselves give most uncertain results as regards any of the forms of sensation. The substantia gelatinosa of the cord is continuous with and of the same structure as that of the medulla. A study of the structure of the substantia gelatinosa favors the view that it is nervous, of actual functional value, and not an embryonic remnant. It is possible that its cells stand in functional relation to the entering fibers, so that from this point of view the substantia gelatinosa may be looked upon as one long sensory nucleus extending from the chief nucleus of the fifth (which is a specially developed part of it) to the lower sacral region of the cord. These conclusions are in accordance with the views of Schiff and others, viz., that the gray matter is the path by which sensory impressions reach the higher regions of the nervous system. This paper attempts to limit this path to the substantia gelatinosa and its plexus. How the stimulus passes up to the cerebrum, whether it straggles up cell by cell or by the intervening fibers of the plexus, is at present unknown.

External Esophagotomy for the Removal of a Foreign Body from the Esophagus.—DUFFAU (*Journal de Médecine de Bordeaux*, No. 47, 1892, p. 522) has reported the case of a man, twenty-one years old, who, on attempting to

run, inadvertently swallowed a large stone that he happened to have in his mouth. Little could be seen externally or learned from exploration of the mouth. On palpation, however, a sense of resistance could be appreciated at the level of the sternal notch, and the passage of a bulbous bougie encountered an impassable obstruction at a corresponding point in the esophagus. Deglutition was extremely difficult; only fluids in small quantity could be swallowed. All endeavors to dislodge and remove the body failed. Better results were not had on the following day, after the patient had rested. It was thus finally determined to perform external esophagotomy. An incision, almost four inches long, was made in the course of the anterior margin of the left sterno-mastoid muscle and extending to the level of the sternum. By careful dissection the esophagus was reached and incised. After some difficulty the stone, which was quite firmly impacted in the esophagus, was removed. The field of operation was rendered aseptic and the margins of the incised mucous membrane were united, the muscular coat not being further disturbed. The sheath of the muscle was closed by suture. The bottom of the wound was now packed with gauze, which was brought out at the inferior extremity of the incision. The remainder of the wound was closed by catgut sutures. After the operation the patient was nourished through the medium of a tube. There were no complications. Nine days after the operation the patient was able to take liquids in the usual way, without any escape from the esophageal wound. In a short time recovery was perfect.

Noma in an Adult.—KÖSTER (*Centralbl. f. Chirurgie*, 1892, No. 45, p. 940) has reported the case of a woman, forty-four years old, who was said to have had a left-sided hemorrhagic pleurisy, from which she recovered, but never afterward felt perfectly well, suffering considerably from dyspnea. The hygienic surroundings were poor; the woman was compelled to work hard, and received insufficient food. A swelling appeared upon the inner surface of the left cheek, and in the course of two weeks the entire cheek was swollen. A few days later a bloody, offensive discharge from the mouth set in. The cheek became intensely red, then black, and finally ulcerous. The edematous swelling extended to the whole of the left side of the face. There was slight elevation of temperature. The urine contained no albumin. The gangrene of the cheek progressed until the cheek was perforated. For a year there had been noticed a tumor in the left hypochondrium, at times larger, at times smaller. The spleen was found to be enlarged. There were 3,200,000 red and 20,000 colorless blood-corpuscles to the cubic millimeter. The condition of the woman became progressively worse, and she died in collapse. At the post-mortem examination, in addition to the gangrene of the left cheek and the adjacent gum, the left pleural cavity was found to be obliterated by adhesions, the spleen enlarged, and its capsule greatly thickened, and the kidneys large and white.

A Gas-generating Bacterium in Urine.—SCHOW (*Centralbl. f. Bakteriol. u. Parasitenk.*, xii, 21, p. 745) has isolated from the urine of a case of compression-myelitis, attended with incontinence of urine and cystitis, a short, plump, motile bacillus, capable of generating carbon dioxid. The urine had been noticed to have a sulfurous odor. In most of the cultures of the organism, for which the name cocco-bacillus aërogenes vesicæ is proposed, a peculiar aromatic odor was developed. Cystitis was produced in a dog by injecting an infusion of the culture into the bladder, and applying a ligature to the urethra for a few hours.

THERAPEUTIC NOTES.

For Purulent Cystitis.—

℞.—Iodoform. subtil. pulv. . . . ℥iv.
Mucilag. acaciæ . . . . f℥jss.
Glycerini pur. . . . . f℥vj.
Aquæ destil. . . . . ad. f℥v.—M.

S.—After irrigating the bladder with a solution of lactic acid, 1:400, five drams of the emulsion indicated are carefully injected and permitted to remain for fifteen minutes. The procedure is repeated during several weeks at intervals of several days.—PHILIPPOFF, *Deutsche med. Ztg.*, No. 93; *Wiener med. Presse*, No. 51.

Analgen, or ortho-ethoxy-ana-monobenzoylamidochinolin ($C_9H_5.OC_2H_5.NH.COC_6H_5.N$) is the name given to a white, tasteless compound that is almost insoluble in water, soluble with difficulty in cold alcohol, but more readily in hot alcohol and in dilute acids, and that melts at 406.4° F. The agent has been shown to be non-toxic to dogs. It has been employed in doses of from seven and a half to thirty grains as an analgesic and antineuralgic and as an antipyretic. The reduction of temperature to which it gives rise is attended with sweating.—*Therapeutische Monatshefte*, vi, 12, p. 666.

For Sycosis.—

℞.—Acid. salicylic. . . . gr. x.
Chrysarobin. }
Ichthyol. } . . āā gr. xxiv.
Vaselin. vel lanolin. . . ℥j.—M.

Ft. unguent.

S.—Apply topically with friction and cover with a thin sheet of rubber cloth.

QUINQUAUD, *L'Union Méd.*, No. 144.

Painful Hemorrhoids may, after being washed with a weak solution of mercuric chlorid, with advantage be anointed with the following ointment:

℞.—Lanolin. . . . . ℥v.
Vaselin. . . . . ℥ij.
Aquæ destil. . . . . ℥iij.—M.

The ointment may also be incorporated in a tampon, which can be introduced into the rectum.

Corr.-bl. f. Schw. Aerzte, xxiii, 2.

Puff ball (Lycoperdon giganteum) as a Hemostatic.—SMITH (*Edinburgh Medical Journal*, No. 451, p. 639) reports the successful employment of puff-ball (Lycoperdon giganteum) in the control of hemorrhage in accessible situations. The puff-ball is cut into thin slices, and applied directly to the bleeding-point or surface.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

LEUKEMIA AND PSEUDO-LEUKEMIA.

NOT a little attention has been devoted during the past few years to the study of the relations of pseudo-leukemia, leukemia, and allied affections, and it would seem that we have arrived at somewhat clearer notions of their mutual interdependence. The close relation of leukemia and pseudo-leukemia is at once evident from the identity, with the exception of the condition of the blood, of the clinical features and from the fact that the pathologic alterations of the blood-forming organs are indistinguishable; yet the single fact of the presence of marked leukocytosis in leukemia has served to maintain this as a separate disease. H. C. WOOD,[1] many years ago, ventured the suggestion that leukocytosis is a feature of too little importance to distinguish one disease from another similar in other respects, but his opinion has until recently found few determined supporters. The reason of this is doubtless to be found in the very striking and unique appearance presented upon microscopic examination of the blood, and the fact that knowledge of the varied conditions that may induce increased numbers of leukocytes in the blood was meager in the day of WOOD'S announcement. We are more fortunate at the present time in recognizing many causes that lead to leukocytosis, albeit of less degree than that seen in leukemia, and this knowledge may aid us in a better conception of the nature of these affections and to divest ourselves of the undue influence with which this condition has, fetish-like, controlled our beliefs.

Beginning with WOOD, a number of observers (MOSLER,[1] FLEISCHER and PENZOLDT,[2] WESTPHAL,[3] SENATOR,[4] EBSTEIN,[5] VON JAKSCH,[6] and more recently RENDU,[7] CROCQ,[8] TOROJE,[9] and PALMA[10]), have recorded cases of Hodgkin's disease that terminated in leukemia. Some of these authors are inclined to regard the increase in the number of colorless blood-corpuscles that occurs at the end of these cases as either a terminal leukocytosis, such as may occur in other diseases (CROCQ), or as an acute leukemia supervening upon a previous pseudo-leukemia (EBSTEIN); but the degree of leukocytosis observed in such cases has far exceeded that which occurs at the termination of other diseases, and the great similarity of the two diseases in all other features would disincline an unbiased mind from accepting the idea of the supervention of a second disease upon the first.

It is further of interest to note that cases of undoubted leukemia have been known to present intervals of freedom from a leukemic condition of the blood, as in the cases of BARR,[11] MACKENZIE,[12] and TOULMIN.[13] If, then, leukocytosis were sufficiently important to justify the view of EBSTEIN and his followers, should we expect to find this symptom absent even for the briefest period during the continuance of the disease? The opinion expressed by others that in the clinical course of true leukemia the anatomic changes in the blood-forming organs may precede definite alterations in the blood by considerable lengths of time, is but a confirmation of the position we maintain, that the

leukocytosis of leukemia is a symptom of too little import to warrant the maintenance of a separate and distinct disease upon this alone.

The opinion here expressed receives further corroboration by a consideration of two other allied affections recently described: the *splenomegalie primitive* of DEBOVE and BRUHL,[1] and the *anemia infantum pseudo-leukemica* of VON JAKSCH.[2] The former is a disease in which there occurs an apparently idiopathic enlargement of the spleen, with anemia and debility, and in which the characters of the splenic enlargement coincide entirely with those of leukemia or pseudo-leukemia. There seems, therefore, no sufficient reason for regarding this other than as Hodgkin's disease of splenic type. The infantile pseudo-leukemia of v. JAKSCH, on the other hand, approaches more nearly to the features of leukemia, with the distinctions that the liver enlarges less, the leukocytosis is less profound, and connective-tissue hyperplasia in the spleen is relatively more marked than in leukemia.

In connection with the present discussion, then, we may group these several diseases together as a sequence, beginning with the primary splenomegaly, in which the spleen alone seems involved; then Hodgkin's disease, with implication of the lymphatic glands as well; next v. JAKSCH's pseudo-leukemia, with further addition of leukocytosis and myelogenous involvement; and finally leukemia, in which all of these changes occur to the maximum degree. Viewed in this way it does not seem unreasonable to suppose that we have in all of these cases to do with more or less identical pathologic processes, the degree alone of abnormality varying in the different forms, and being somewhat differently disposed; and this is all the more probable as cases of Hodgkin's disease, as well as primary splenomegaly (CROCQ), have been known to become leukemic, and cases of leukemia, temporarily at least, pseudo-leukemic. If, however, it be urged that the different histology of v. JAKSCH's pseudo-leukemia (the great connective-tissue hyperplasia and absence of lymphatic proliferation) excludes this from the present discussion, have we not, on the other hand, a striking example here of the possibility of extreme leukocytosis (almost as great as in the most pronounced leukemias) aside from leukemia itself? and would not this render increase of leukocytes (properly, as we think) an unimportant symptom, as far at least as establishing a separate disease by its occurrence is concerned?

EICHHORST[1] sought to establish for leukemia an independence by noting the constant occurrence of excess of uric acid in the urine in this disease, and the absence of the symptom in pseudo-leukemia, but the investigations of HORBACZEWSKI[2] and WRIGHT[3] have undoubtedly proved that the excessive uric acid in the urine is merely the result of excess of leukocytes and their destruction in the blood.

We cannot hesitate, therefore, to range ourselves with WOOD,[4] JACCOUD,[5] HENRY,[6] ORTNER,[7] TISSIER,[8] and those others who deny that these affections are essentially separate, but are convinced that they are expressions of the same underlying conditions, whether these be constant or variable.

There is, indeed, no little evidence to incline us to the view that these diseases, pseudo-leukemia and leukemia, are both, after all, but expressions of various pathologic states, whose visible symptoms and gross morbid changes are similar. Thus, in the case of leukemia there is apparently wide difference between the ordinary chronic form of the disease and the interesting cases of acute type, particularly such as those of OBRASTZOW,[9] in which infection and contagion were clearly shown; and no less impressive are the studies of pseudo-leukemia by WAETZOLDT,[10] ASKANACY,[11] and BRENTANO and TANGL.[12] These observers showed clearly that the enlarged glands of cases of pseudo-leukemia contained tubercle-bacilli, and in one case at least were infective for guinea-pigs. Whether or not we accept as conclusive two of these cases, about which the doubt might be entertained that there was secondary tuberculous infection of the enlarged glands, there can be no question of the third, that of ASKA-

NACY, and we are forced to believe that the manifestations of pseudo-leukemia may sometimes result from lymph-gland tuberculosis. In another carefully studied case (ROUX and LANNOIS[1]) the glands contained the staphylococcus pyogenes aureus, and the glandular proliferation seemed dependent on this microörganism. Finally, the relation of lymphosarcomatosis, as in the cases of ORTNER[2] and of PALMA,[3] to leukemia and pseudo-leukemia, and the striking difference in the spread of this new-growth from that of the ordinary lymphomatous growths of these diseases, are facts suggestive of a varied pathology.

A careful consideration of the present knowledge concerning these diseases would indicate, then, that too much stress has been laid upon the occurrence of leukocytosis, and that we are warranted in accepting JACCOUD'S[4] grouping of both under the term *diathèse lymphogène*, whether we believe the cause of such diathesis to be a constant or a variable one.

THE TAX ON ALCOHOL.

OF all forms of injustice, fraud, and extortion, the robbery of the sick is perhaps the meanest. Physicians should, therefore, at once and in no uncertain manner make their influence felt against the bill (H. R. 9829) introduced by MR. SCOTT and now pending in Congress, to increase the tax on distilled spirits from 90 cents to $1.25 per proof-gallon. Its aspects as a revenue measure do not come within our province to discuss; if they did, we could easily expose its fallacy and shortsightedness. What concerns THE NEWS as a medical journal is that the passage of the bill will greatly increase the cost of all drugs and pharmaceutical preparations into the manufacture of which alcohol enters directly or indirectly; and this means almost all of the preparations used in medicine. It is alleged, with great plausibility, that the bill is framed solely in the interests of that gigantic conspiracy popularly known as the Whiskey Trust; the inevitable economic result being to immediately and enormously increase the actual and prospective revenues of the Trust by the advance of 35 cents per gallon in the price of all the stock at present in its possession, bonded or otherwise; and further to increase the disadvantages imposed upon the lesser capital of distillers who still remain "out" of the Trust; thus helping to crush out the last vestige of competition.

In circulars issued by the Philadelphia Drug Exchange, the Drug-Trade Section of the New York Board of Trade and Transportation, and the National Wholesale Druggists' Association, the methods of the Trust are exposed; and it is shown that so far from increasing the tax on all distilled spirits, Congress should provide for the exemption of alcohol used in the arts or manufactures from even the present tax, as is now done in France and England, and thus enable our manufacturers to meet foreign competitors on more nearly equal terms. Furthermore, it is wisely suggested that a just measure of relief would be the reduction of customs duty upon alcohol from the present prohibitory figure of $2.50 per proof-gallon (equal to $4.70 per wine-gallon) to a figure slightly in excess of the present internal revenue tax, say to $1 00 per proof gallon, as there would then be a limit to the exactions of the Trust; for excessive increase of price would invite foreign competition. Even at this proposed reduction the customs duty would afford a protection of $18\frac{4}{8}$ cents per wine-gallon—"surely sufficient for an article costing 25 cents to produce."

It is greatly to be hoped that the Trust will be found to have overshot its mark; and that not only will the great injustice it proposes not be consummated, but that as a result of the interest aroused Congress will adopt the suggestion of affording relief by exemptions and by reduction of tariff, thus putting an end to the inordinate extortion now practised and sought to be increased.

HYDROGEN DIOXID.

IT is now thirty-five years since BENJAMIN WARD RICHARDSON introduced into practical medicine the use of aqueous and ethereal solutions of hydrogen dioxid (H_2O_2). It is not much more than five years since various American observers have been singing the praises of the agent, with utter disregard of the observations of the man who introduced it and pointed out all its applications and limitations. One thing in particular he showed as the result of prolonged experimentation; namely, that it was impossible to prepare a stable solution in water of more than ten-volume strength. If solutions of greater strength were attempted, it was necessary to render them too acid, and as soon

[1] *Roux and Lannois:* Rev. de Méd., December, 1890.
[2] *Ortner:* Loc cit.
[3] *Palma:* Loc. cit.
[4] *Jaccoud:* Loc cit.

as uncorked they began to lose oxygen; rapidly running down to almost nothing more than H_2O, *i.e.*, hydrogen monoxid—water. Nevertheless, American manufacturers have refused to learn from the great authority of Richardson, and they continue to advertise solutions of more than ten-volume strength. Analyses published in THE MEDICAL NEWS prove the incorrectness of the advertised claims, and the experience of practitioners (excepting those who have by this time become well-recognized as manufacturers' reporting agents) shows that few of the preparations now in the American market can be depended upon; their reliability being, as a rule, in inverse ratio to their respective claims. A moderate acidity is necessary to any stable preparation, even of ten-volume strength; but this is so slight that except for subcutaneous injection it may be disregarded. The preparation now most often supplied on prescription in this city, however, is so highly acid that it gives pain if used, and does harm, for instance, in the throat, especially in children. But in the treatment of diphtheria, of scarlatina, and of various forms of sore throat, hydrogen dioxid is invaluable; and it is repeated experience of the harmfulness of the preparation alluded to that leads to the writing of these lines. If no other preparation can be obtained, the acid should be carefully neutralized with ammonia water or sodium bicarbonate, at the time of using. The subject is an important one, and every physician should personally study it. Two facts should be borne in mind; no preparation that undiluted gives pain should be employed; no preparation claiming more than ten-volume strength can be entirely reliable. As even ten-volume solutions must often be diluted, the necessity for stronger ones is not apparent.

We have for many years used a preparation made in London according to Richardson's directions, but the necessity for special importation renders it unduly expensive. American chemists can do as well as English chemists, if they choose, and they ought to be made to choose.

EDITORIAL COMMENTS.

Physicians as Pharmacists.—It is an admitted axiom in mathematics that "the greater includes the less." It is no less true in all other sciences. The study of pharmacy does not include all the knowledge necessary for the practice of medicine, but the study of medicine does include all the knowledge necessary for the practice of pharmacy, in so far as the protection of the public against danger of mistake is concerned. The manipulative skill that comes by practice is not difficult to obtain, and many physicians, especially country doctors, possess this in a high degree.

For this reason the proposition to repeal Section 11 of an act entitled "An Act to regulate the practice of pharmacy, etc," now pending in the Pennsylvania Legislature, is not only unwise and unjust, but ludicrous. The section in question permits any graduate in medicine, of not less than three years' experience in his profession, and legally qualified to practise medicine in Pennsylvania, to act as a pharmacist without special examination. This wise permission should not be repealed. Why a man who can be trusted to prescribe poisons cannot be permitted to dispense them on others' prescriptions is difficult to comprehend. It is like prohibiting a general of the army from serving as a private. He can order the movements of troops but must not handle a musket. Medical men in Pennsylvania should not permit such an absurdity to disgrace our statute books. Somebody, however, is interested in pushing it, and it will probably be necessary to send formal protests, and perhaps delegations to Harrisburg to prevent the attempt from being successful.

"The American Family Physician's Company."—There have been few more ludicrous attempts to commercialize medical practice than the unblushing attempt to establish in Cincinnati, Ohio, a company to act as go-between, promoter, advertiser, and business manager of the physician in his relations with the patient. These enterprising gentlemen proposed to provide "an absolute and sure method of providing a physician of the highest standing for sickness and accident to any and all members of the family." All one had to do was to "go to the nearest telephone," touch the button—and the company did the rest. The scale of prices for every sort of service was laid out with most commendable accuracy. Unluckily, however, for the medical tradesmen, the Academy of Medicine and the Cincinnati Medical Society said that "a physician cannot be connected with this company and remain a member in good standing of the medical societies." Now, let those "physicians and surgeons of the highest professional standing" reorganize themselves, as our St. Louis friend would say, on "broad-gauge principles," and institute a telephone or call-bell service, similar to that ingenious one in use in the hotels, whereby the guest can have appear at his door anything from a glass of fizz-water to a human being with any peculiar capacity desired. In this way the pointer could be turned to any one of the thousand symptoms of disease, belly-ache, acute vaginismus, paralysis, albuminuria, or hysteria—and lo! there would at once be whisked to one's relief the accurate and infallible machine, human or not human, Hahnemannian, electric or allopathic, the exact drug or potion, all prepared and ready to be shot at or into one, exactly *quantum suf.* and *pro re nata*, to a dot! "All accounts must be settled at the office."

Medical College Consolidation.—The action of the authorities of Rush Medical College and of the College of Physicians and Surgeons, of Chicago, in offering to resign their various positions unconditionally and to sur-

render their property to the liberally-endowed new Chicago University, must be viewed as most significant. With this great school in the West, with the fine plant and the large resources of the Johns Hopkins School at Baltimore, with the consolidation of two of the schools in New York, Philadelphia must look to her laurels, lest she be left in the race. Who shall say that good might not result if the dream of Provost Pepper were realized, that medical students in Philadelphia could, at their option, attend lectures at one or another of the reputable and high-grade schools of the city. The demand of the hour is for higher medical education, and this implies preliminary qualifications, protracted courses of study, unselfishness of administration, and liberal endowment. There is needed a healthful reaction against the petty rivalries and ignoble strifes of institutions supposably working for a common noble end. If the supposed object—the highest and best medical education—were the real and primary object we should hear more of such attempts to gather the weak, selfish, and warring forces into a unity whereby progress in medicine would be admirably furthered, and a silly rivalry be no more the butt of ridicule and public scorn.

Tuberculosis and Life-insurance —It is a very regrettable fact that the vast amount of data in reference to the problems of heredity and preventive medicine that might be elicited from the vital statistics of life-insurance companies is not utilized; and still more regrettable is it that the members of the medical profession connected with these companies do not make better use of their positions and powers to so shape their examinations and records as to throw still greater light on these problems. It would, perhaps, be somewhat of a thankless task on their part, but what downright good work in the world receives proper gratitude and reward? Dr. Lyon recently read before the Hunterian Society, of London, a thoughtful essay on "Phthisis in Relation to Life-insurance," in which we are somewhat surprised to find that medical records contain no adequate data for determining the question of pulmonary tuberculosis in relation to life-insurance, and that the existing theories are founded upon insufficient data. A thorough-going examination of the statistics of insurance offices is urged as highly necessary.

The Medical Education of Missionaries.—The International Medical Missionary Society has asked the New York Board of Regents to empower the Society to grant its students the degree of M.D. after such medical education as it shall deem sufficient to fit them for their work. It seeks to supply a medical course and degree at a less expense than the regular colleges. A less expensive course of study (at the low-tuition rates of our colleges) means, of course, a less thorough course and a more poorly-prepared physician. Worse-qualified physicians and a multiplication of third-rate or tenth-rate medical colleges are things far from desirable. It is difficult to understand why the physician plus the missionary, separated, as he will be, from the aids and supports of civilization, should be less thoroughly equipped for his medical work than the physician who, without theology, practices with physicians and drug-stores, and instrument-makers all about him.

A Cheap Advertisement.—All it costs to have portrait and "biography" inserted in *America Illustrated* is $16.75, and one can write his own puff! The portraits, judging from samples forwarded, are really well done, and we cordially commend the scheme to all eligible "medical men" that find pleasure or profit in being thus advertised. If in enterprises of this character like sketches were printed, concerning those who did not "subscribe" or pay for "engraving," as those who do pay, nothing could be said against any one concerned; it is the restriction of "notice" to those who give *quid pro quo* that makes it advertising, and as such to be avoided by self-respecting physicians.

Medical Students and Medical Sectarianism.—From the forthcoming report of the Bureau of Education Dr. Holmes (*Journ. Amer. Med. Assoc.*, January 14, 1893) epitomizes the statistics of medical education in the United States. In 1890 there were 13,044 students at the regular schools, against 1128 at the homeopathic, and 661 at the eclectic schools. The number of homeopathic students, compared with that of former years back to 1880, is decreasing; the number of the eclectics is slightly increasing, whilst the number of regulars has enormously increased—about 2300—within three years.

Speech Without a Larynx and Without Use of the Lungs.—We are informed by Dr. J. Solis-Cohen that the patient from whom he removed the larynx last April, and whose trachea has been continuously cut off from intercommunication with the mouth, has learned, by practice, to so draw together his palatine folds as to make them subserve the purpose of phonal reeds, which he sets into vibration with the air in his mouth and pharynx. He can thus articulate words and short sentences quite audibly, and at times loudly enough to be distinguished in an adjoining apartment. The voice is phonal, and not a mere whisper.

SELECTION.

MEDICAL EDUCATION.

In 1880, in each 100,000 inhabitants in France, there were 11 students of medicine and 14 students of law. At about the same time, in Germany, there were 8 students of medicine and 11 students of law to the same unit of population. This changed so that in 1888, France had 17 students of medicine and 14 students of law, and Germany had 18 students of medicine and 13 students of law to each 100,000 population.

In 1881, in the United States, there were 25 students of medicine, 6 students of law, and 9 students of theology to each 100,000 inhabitants, while in 1890 there were 24 students of medicine, 7 students of law, and 11 students of theology in the same unit of population.

Relatively a smaller number of medical students have the bachelor's degree than in 1880, though the education of the average medical student is superior to the education of the average medical student ten years ago.

Last summer, many of the college journals gave in the June number the statistics of the graduating class. I selected out seven such compilations and noticed an astonishing series of figures under the caption "Prospec-

tive Calling." Almost 40 per cent. of the June graduates were put down for law, about the same number for theology, while only about 5 per cent. had selected medicine for their future study.

This shows evidently that medicine is not attractive to the college-bred man.

But if medicine is sought by the educated German and is neglected by the educated American, may it not be the fault of the medical schools themselves? Largely I believe it is. This has happened from many and from widely separated causes. Medical education has not been controlled by educators, but by clinicians. The antique methods of the Revolutionary period prevail in the great majority of medical schools to-day. Even in those medical schools that are most intimately connected with State or private universities, other rules and other methods than those of the literary and technological departments prevail. In the report which furnishes the material for this article, we are astonished to find that in one of our university medical schools the course of lectures is so arranged that each student hears every lecture repeated the second year of his attendance and then passes his examination and graduates. Can any educated man endure this, in this last decade of the nineteenth century! The fact is apparent to any student that medical schools are run for the good and profit if not for the glory of the professors. These men want quick returns, and they adapt their instruction to the unevolved mental maws of the students that come in the greatest numbers. Such pap the college-bred man does not relish. To such instruction the university teachers do not recommend men for post-graduate work. To such instruction the American university too often gives its name though withholding its support.

In conclusion, let me make the following deductions:

1. The average course of study in the United States is still less than three years—*i. e.*, eighteen months.

2. The antiquated method of repetition still prevails in the majority of medical schools.

3. The number of students of medicine is absolutely increasing, but (in relation to the population) relatively diminishing. The homeopathic and eclectic schools are hardly holding their own.

4. The education of the average medical student is superior to that of ten years ago, but the ratio of matriculates having degrees in science or art is actually diminishing even in the richest, best located, and only endowed medical schools.

5. The medical department is, so far as we know, neglected by every university in the United States; it is farmed out or left to shift for itself on half rations, or in the best instances, treated from an educational standpoint in an exceptional manner.

6. Medicine is neglected by the benevolent and by the State. From the former it has received almost nothing, and from the latter not a tithe of what has been lavished on technological schools, and this in spite of the fact that the State and all benevolent institutions have put a heavy task of gratuitous and often compulsory service on the medical profession.

7. The medical schools are wasting their substance by keeping their doors shut half the year, and they are degrading the profession by allowing uneducated men to matriculate and uncultured men to graduate.

8. The laws which allow the diploma to become a license to practise, but the short-term-no-requirement schools in a position to dictate to the schools that offer a medical education in place of a degree.—BAYARD HOLMES (*Journal of American Medical Association*, January 14, 1893).

NEWS ITEMS.

The U. S. Marine-Hospital Service.—A board of officers will be convened at Washington, March 20, 1893, for the purpose of examining applicants for admission to the grade of Assistant Surgeon in the U. S. Marine-Hospital Service.

For information or invitation to appear before the board of examiners, the Supervising Surgeon-General, Dr. Walter Wyman, Washington, D. C., should be communicated with.

The Section on Laryngology and Rhinology of the Pan-American Medical Congress, it is announced, is now thoroughly organized, with secretaries in all the countries of South America, as well as in the United States and Canada. Dr. J. Maron y Alonso, of Las Vegas, N. M., is the Spanish-speaking secretary, and Dr. T. Morris Murray, of Washington, D. C., is the English-speaking secretary, with whom physicians interested in this section are invited to correspond.

Ohio State Association of Railway Surgeons.—An invitation is extended to all railway surgeons of the State of Ohio to attend a meeting to be held on March 17th, at 9 A.M., in the amphitheater of the Ohio Medical University, at Columbus, for the purpose of organizing a State Association. Intending participants are requested to send their names to the secretary, Dr. C. H. Merz, Sandusky, Ohio.

The Cholera in Marseilles.—Dr. Robin, of Paris, has written the New York *Herald* that the epidemic in Marseilles, about the exact nature of which there has been considerable doubt, is in his opinion genuine cholera, but that there is no immediate danger of a spread of the disease from this point as an infecting center.

Addition.—By an inadvertence the name of Dr. Middleton Michel, of Charleston, was omitted from the list of members elected at the last meeting of the Association of American Anatomists, as published in THE NEWS of January 28, 1893, p. 109.

The American Practitioner and News is to be congratulated upon its greatly improved appearance. Its dignity and usefulness would be still further increased by omitting advertisements from its reading-columns.

Prof. Otto Kahler, the occupant of the chair of clinical medicine, associated with the second medical clinic in the University of Vienna, died January 25th, forty-four years old, of carcinoma of the tongue.

The Missouri Valley Medical Society will hold its next meeting at St. Joseph, Mo., March 16th. A cordial invitation is extended to the members of the profession to attend.

VOL. LXII. SATURDAY, FEBRUARY 25, 1893. No. 8.

ORIGINAL ARTICLES.

REPORT OF SEVEN CASES OF RUPTURE OF THE URINARY BLADDER, WITH OBSERVATIONS ON DIAGNOSIS.[1]

BY JAMES B. HERRICK, M.D.,

PROFESSOR OF THE PRACTICE OF MEDICINE AND THERAPEUTICS, WOMAN'S MEDICAL SCHOOL, CHICAGO; ADJUNCT PROFESSOR OF MEDICINE, RUSH MEDICAL COLLEGE, CHICAGO.

OF the following cases, I myself saw the first three and assisted in their treatment. I am indebted for the privilege of reporting these three to Drs. T. J. Conley, Bayard Holmes, and C. W. Earle, in whose hospital or private practices they occurred. Dr. Henry F. Lewis furnished me with the facts concerning Case IV, and Dr. Ludvig Hektoen, with those of Case VII. Cases V and VI occurred in the Cook County Hospital service of Dr. W. F. Knoll, by whom the histories were kindly placed at my disposal. I desire to thank all these gentlemen for their courtesy in thus enabling me to get together these interesting cases.

CASE I. *Traumatic rupture of the bladder; peritonitis; celiotomy; death.*—John D., aged twenty-eight, a well-developed, muscular man, was admitted to Cook County Hospital on the afternoon of May 31, 1889, in the service of Dr. T. J. Conley. He gave a clear, intelligent history of having been kicked in the supra-pubic region by a horse, twenty-four hours before. At that time he had not been intoxicated. He had urinated four hours before receiving the injury. Since then he had not passed a drop of urine himself, though a physician had withdrawn by catheter a "cupful of bloody water" five hours before the patient entered the ward. He complained of quite severe abdominal pain and of nausea. He was vomiting when admitted, the face was flushed, the skin not clammy, the mind clear. The breathing was rapid and almost entirely thoracic; the pulse 120, regular, quick, and the temperature 100° F. The abdomen was moderately tympanitic, the muscles tensely contracted, and there was an absence of hypogastric dulness. There was neither desire nor ability to expel urine. By the catheter a few drops of bloody fluid were obtained, and pressure over the abdomen forced out about a dram more. With the sound, no abnormal opening in the bladder could be discovered. Rectal examination revealed no fracture of the pelvic bones. Intra-peritoneal rupture of the bladder was diagnosticated, and as a confirmatory test 600 c.c. of boric acid solution were injected through the urethra, of which but 100 c.c. were recovered. Though previous to the introduction of the solution of boric acid, a Barnes dilator had been introduced into the rectum, no increase in dulness was noted in the hypogastrium, such as would have been found had the bladder held the fluid and been lifted against the anterior abdominal wall by the dilator.

Twenty-three hours after the reception of the injury, abdominal section was made and a linear rent in the posterior vesical wall near the fundus was repaired by suture. The parietal and visceral peritoneum showed injected vessels, loose adhesions, and an abundant flaky fibrinous exudate. Abdominal flushing and drainage were carried out.

Urine was voided voluntarily five hours after the operation, and again five hours later. During the remaining twelve hours of life no urine was obtained by voluntary micturition or by the catheter. Death followed at eight o'clock on the morning of June 1st, forty-nine hours after the injury, and twenty-four after the operation.

Immediately after death the abdominal wound was opened. The stitches in the bladder were almost concealed from view by the exudate covering the line of the wound. The bladder held without leakage a pint of water. There were general peritoneal adhesions, and there was a small amount of slightly fetid fluid in the lowest portion of the abdominal cavity.

CASE II. *Traumatic rupture of the bladder; celiotomy; septic peritonitis; death.*—(Service of Dr. Bayard Holmes, Cook County Hospital.) M. F., an adult male, on the morning of July 10, 1889, while intoxicated, fell a distance of twelve feet, striking on the feet and left hand, and cutting the chin. He immediately felt considerable pain in the abdomen, which grew steadily more severe. He evacuated both bladder and rectum an hour after the injury, but did not notice the character of the excreta. The patient was sent by the examining physician to the ward for minor surgery, where the wounds were attended to by the nurse. In the evening the interne, noticing a tense and tender abdomen and dulness in the hypogastric and left inguinal regions, inserted a catheter and drew off a pint and a half of dark bloody fluid, which flowed in quite a steady stream and coagulated soon after withdrawal. At 10 P.M., under ether, no pelvic fracture was detected. A sound passed by the urethra revealed a roughness in the fundus of the bladder. Celiotomy was performed, and a ragged rent, two inches in length, was discovered in the fundus, a little to the right of the median line, and just beyond the place of deflection of the peritoneum over the bladder. The lower half was sutured, and the margins of the anterior half were stitched to the

[1] Read at the meeting of the Pathological Section of the Chicago Academy of Sciences, December 1, 1892.

lower angle of the abdominal wound. A rubber drain was inserted into the bladder.

In spite of what seemed to be delirium tremens, and a general septic peritonitis (the latter confirmed by autopsy), the patient lived four and a half days after the operation.

CASE III. *Traumatic rupture of the bladder; peritonitis from catheter-infection; death.*—On the evening of May 18, 1890, there was brought to Dr. C. W. Earle's hospital for inebriates, a man who for several days had been drinking heavily. About ten o'clock on that evening, I saw him and had no suspicion of anything more than ordinary drunkenness. The next morning the nurse said the patient had complained of severe pain during the night, and had often gone to the closet to urinate. The man, who was now sobering up, could not remember when he had last urinated, though he said that during the night he had frequently felt the desire to empty the bladder. Suspecting retention of urine, I introduced a metal catheter (about No. 10, American), which passed readily, meeting no obstruction, and there escaped a dark, reddish fluid, containing, as shown by microscopic examination, a large number of red blood-corpuscles. The stream was an interrupted one, varying in the distance it was thrown from the catheter's end with the movements of respiration, and thrown, when the muscles of the abdominal wall were brought into play in the efforts of the patient to force out the fluid, for at least four or five inches. In this way, and by pressure upon the abdominal wall, something more than a quart of bloody fluid was withdrawn. There was dulness on percussion, now only faintly preceptible in the flanks, while before it had been noticeable near the median line, though before catheterization there had been no flatness on percussion made out, nor any rounded mass, such as the distended bladder gives rise to.

The history of the patient was valueless, as he remembered nothing of the events of the preceding days. The remains of a recent bruise were discovered on the right knee, and a friend reported that on the 17th a physician had been called, who prescribed for severe abdominal pain. No history of injury was obtainable. The temperature at the time of catheterization was 99° F., and the pulse 120. Rupture of the bladder was diagnosticated. A consultant advising against operation, the patient was put on stimulants, and kept quietly in bed.

The urine was frequently drawn by the nurse and always escaped when the patient brought the abdominal muscles into play, or when pressure was made over the abdomen, both of which actions caused no pain. The temperature never rose as high as 100° F. Gradual failure in strength occurred, and the patient died on the morning of May 21st, fifty-four hours after admission to the hospital and about four days after having been seen by the physician who prescribed for the severe abnominal pain.

A post-mortem examination was made twelve hours after death. The skull was not opened, and examination of the chest was negative. About one pint of clear, blood-tinged fluid was found free in the abdominal cavity. The visceral and parietal peritoneum presented a normal naked-eye appearance, except in the lower abdomen, where, in the most dependent position as the body lay on the back, *i. e.*, next the posterior wall of the abdomen, there were injection of vessels and a very few loose adhesions between the coils of the intestines, and a slight amount of fibrinous deposit. The posterior wall of the bladder showed a gaping wound, with irregular edges, extending from above downward and to the left, over two inches, and involving all the coats of the viscus. Other organs gave negative results, save that one kidney showed the changes incident to chronic interstitial nephritis.

CASE IV. *Extra peritoneal rupture of the bladder; abscess; death.*—The patient was admitted to Cook County Hospital moribund, with no history obtainable, save that he had been ill for several days with pain in the lower abdomen. He died in a few hours, no ante-mortem diagnosis having been made. The autopsy showed extra-peritoneal rupture of the bladder and localized suppuration.

CASE V. *Fracture of the pelvic bones; extra-peritoneal and intra-peritoneal rupture of the bladder; death.*—(Cook County Hospital, service of Dr. W. F. Knoll.) Maggie M., twenty-eight years old, fell thirty feet on January 13, 1891. Immediately brought to the ward, she was unconscious, breathing heavily and rapidly, bleeding from the ear, and with a feeble pulse. Three ounces of bloody urine were drawn by the catheter. But two-thirds of a solution of boric acid, injected into the bladder, could be recovered.

Incision over the arch of the pubis revealed laceration of the anterior wall of the bladder, and through this a laceration of the posterior wall could be diagnosticated. A comminuted fracture of the pubic bone gave a ready explanation of the damage to the bladder. Bloody fluid was extravasated into the pericystic cellular tissues and into the peritoneal cavity. The wounds were repaired, the patient taking the anesthetic poorly. She never regained consciousness and died on the evening of the same day. No autopsy was permitted.

CASE VI. *Extra-peritoneal rupture of the bladder; operation; death on the fifth day.*—(Cook County Hospital, service of Dr. Knoll.) M. K., an adult, painter, was admitted February 10, 1891. A mass of iron had struck him on the left groin and left side of the pelvis. On admission the general condition was good. There was swelling along the line of Poupart's ligament on the left side, from the root of the penis to a point two inches above the anterior superior spine. There was inability to urinate. One ounce of bloody fluid was withdrawn by the catheter. Injection of solution of a boric acid caused increase in size of the swelling, and none of the solution was recovered.

Incision in the median line, as in supra-pubic lithotomy, showed a fracture of the body and ramus of the os pubis, extravasation of bloody urine and boric solution. As the seat of the rupture was out of reach, a lateral perineal incision was made and a rent at neck of the bladder was discovered.

The patient lived for five days, with rapid pulse, averaging 130, and a temperature ranging from 99°

F. to 102° F. He complained of but little pain; the wounds were of a healthy appearance, the dressings always freely soaked with urine. On the morning of the fifth day a severe chill occurred, with rise in temperature, delirium, collapse, and death at 10.30 P.M. No autopsy was permitted.

CASE VII. *Traumatic intra-peritoneal rupture of the bladder complicated by uterine fibroids and cerebral hemorrhage; death after nine days; no peritonitis.*—A woman, thirty-five years old, suffering from severe pain in the head, was admitted to hospital on June 11, 1892. During the afternoon she had a fainting spell, and at about this time was kicked in the abdomen and beaten over the head with a broom by her drunken husband. On June 14th a physician found her suffering with severe headache and unable to answer questions. On the following night she walked about the room screaming, and on the 20th she died, without the development of any new symptoms.

The post-mortem examination, made twenty-four hours after death by Dr. Hektoen, who reports the case, showed no external mark of violence. The abdominal cavity contained three and one-half quarts of clear, limpid fluid with a urinous odor. The peritoneum was smooth, shining, and showed no evidence of peritonitis.

In the posterior wall of the urinary bladder, near the fundus, was a transverse tear, one and one-half inches long, with ragged margins free from any signs of inflammation, and showing on the mucous surface a few superficial continuations at the end of the total tear; the viscus was empty, the mucous membrane smooth, the walls apparently thin. The uterus contained three sub-serous fibro-myomata, the largest of a diameter of four inches, the pelvis being filled up. Heart, lung, kidneys, liver, spleen, showed no changes bearing upon this lesion.

In the left frontal lobe of the brain was a blood-clot, the size of a hen's egg, in a cavity lined with softened yellowish detritus. The pia mater in the longitudinal fissure was infiltrated with blood; the brain otherwise healthy.

REMARKS.—Out of a total of about eight thousand surgical cases in Cook County Hospital since 1889, five have been proved to be instances of traumatic rupture of the bladder. Two of the seven cases here reported were not diagnosticated before drath. This frequency of occurrence and failure to diagnosticate render it probable that the accident happens more frequently than is generally supposed. The *St. Bartholomew's Hospital Report* for 1869–75 mentions but two instances of injury to the bladder out of a total of 16,711 surgical cases.

The cases here recited are instructive, not so much from the point of treatment as from that of diagnosis. Incision and repair of the wound in intra-peritoneal rupture, and repair of the wound when possible, with drainage, in extra-peritoneal rupture, are probably regarded to-day as the rational treatment.

The history of a trauma can usually be obtained. If the patient himself, on account of intoxication, cannot remember an injury, bruise-marks can often be discovered, as in Case III, pointing to blows or falls. These may, however, be lacking, as in Case VII. In Case I, too, there was discovered only a slight area of subcutaneously extravasated blood when the abdominal incision was made. In rupture of the healthy bladder traumatism is to be assumed. When a weakness of the coats of the viscus exists, as from tuberculous or malignant disease, or from inflammatory changes in the wall of the bladder, or in its neighborhood, over-distention without trauma may cause rupture. Some, as Pousson, believe that an over-distended healthy bladder may rupture spontaneously. That drunkenness is an important etiologic factor is well known. It furnishes the abundant secretion of urine; a paretic, and consequently distended, bladder, which rises above the pelvic brim, where it is exposed to injury; and a relaxed abdominal wall, so that the force of any blow, to which a drunken man is especially liable, be it from a kick, a heavy weight, or a fall, comes with unchecked vigor upon the viscus with walls tightly stretched. In Case VII, as Dr. Hektoen points out, the enlarged uterus constituted a resisting body against which the bladder would be forced by the kick. A slighter blow might here suffice to cause rupture, and especially as the bladder, though not containing much urine, would be lifted by the uterus high in the pelvis.

Two of these seven cases occurred in intoxicated persons. In three, intoxication was not present. In one, the history in this respect is lacking. In Case VII rupture occurred probably some time after a cerebral hemorrhage, when the bladder can easily be assumed to be distended.

Drunkenness is not only an important element in etiology, but it tends to mask otherwise plainly-marked symptoms. The severe pain and the phenomena of shock, so commonly present, may, in an intoxicated person, be but slightly, if at all, marked. The inability to urinate in response to urgent desire, which condition is so characteristic of rupture in a person with unclouded intellect, is often overlooked in these cases by the patient, and, consequently, by the physician. When it is discovered the physician naturally passes the catheter and obtains no urine, or bloody urine.

I desire to call attention to one fact very strikingly illustrated by two of these cases. In Cases II and III there was a free discharge of fluid on the introduction of the catheter. In Case II, Dr. H. F. Lewis, who reports it,[1] says: "The catheter drew about a pint and a half of dark, bloody fluid, which flowed normally after withdrawing the point a short distance and re-introducing." In Case III, a quart

[1] The North American Practitioner, September, 1889.

of bloody fluid was withdrawn in a full stream, which, when the patient strained, was thrown four or five inches from the end of the catheter. The explanation of this occurrence seems to be that in both these cases the rent in the bladder wall, as was shown by ante-mortem and post-mortem examination, was so large that the catheter passed directly into the abdominal cavity, which contained the fluid. Pressure was made by voluntary contraction of the abdominal walls and diaphragm, just as is so often done by a patient when tapped for abdominal ascites. The diaphragm and abdominal muscles were readily made to contract, because at this time, at least in Case III, there was no peritonitis, causing the involuntary fixation of these muscles in order to avoid pain. This point, that when the rent is large, and especially when there is no peritonitis, bloody urine may be obtained in quantity and in a stream, seems worthy of careful consideration, as it is generally stated that no urine, or only a few drops of bloody urine, can be obtained by the catheter. Greig Smith, for instance, in his excellent article, says: "Only blood, or blood and urine, escapes in drops, and the patient gets no relief" (from catherterization).[1] The fact that in Case III the urine flowed, decided, at a consultation, against the diagnosis of rupture of the bladder, and hence against operation.

That peritonitis is not an inevitable consequence of rupture of the bladder is not only known by *à priori* reasoning, on the ground that aseptic urine will not produce peritonitis, and from well-known experiments, but is also clearly shown by these cases. Case III had no sign of peritonitis until he had been catheterized, and this by at least five different persons, and with poor or no antiseptic precautions. The autopsy showed commencing peritonitis in one place only, and that the most dependent portion of the abdominal cavity, when the patient was in the dorsal position, which he kept after the catheterization. Before that he had been up and down, and urine must have bathed all parts of the peritoneum; yet no peritoneal inflammation existed except where the infection by the catheter had taken place.

No case is more positive and instructive, however, than Case VII; here no catheterization had been performed, urine had accumulated in the abdominal cavity for nine days, and yet there was no peritonitis.

We can explain on no other ground than non-existence of early peritonitis the case of Harrison, in which the patient on the day after the rupture walked three miles to be catheterized, and kept at work three days more, emptying the bladder voluntarily. Only on the fourth day did symptoms of peritonitis develop, with death on the eighth day. There were local peritonitis and sac-formation by adhesions.[1] Gillespie reports a case in which, three days after the injury, a patient entered the hospital to be catheterized. Death occurred ten days later. The autopsy showed a ruptured bladder, intra-peritoneal extravasation of urine, and slight peritonitis.

The importance of being careful in catheterizing a patient with suspected damage to the bladder is emphasized by these cases. A septic catheter used for diagnosis may spoil the favorable result of a faultlessly aseptic celiotomy for the repair of the bladder-wound.

In four of these cases the injection of a solution of boric acid, with failure to recover a large part of the fluid injected, confirmed the diagnosis. The exploration of the hypogastrium in all these cases failed to reveal the physical signs of a distended bladder. When enough fluid is injected in this way the ordinary physical signs of abdominal ascites are obtained. In Case VI, the fluid escaping through an extra-peritoneal tear caused the swelling along Poupart's ligament to increase in size. Sterilized water would answer the mechanical purpose and avoid the risk of poisoning from retention and absorption of the boric-acid solution, and would not be as irritating to the sensitive peritoneal pericystic tissue. Keen[2] advocates, as an aid in establishing the diagnosis of intra-peritoneal rupture of the bladder, the introduction of sterilized air *per urethram*, after the analogy of the Senn rectal insufflation. This should give positive aid in extra peritoneal rupture, if there be swelling, tympanites on percussion, and the tissues be emphysematous on palpation. It might have the advantage, too, over the fluid, of escaping through small openings that were closed against fluid by a valve-like flap of membrane, inflammatory exudate, or hernial protrusion of intestine into the bladder.

The attempt has not been made to discuss at length the diagnosis of rupture of the bladder, but rather to give emphasis to some points that are exemplified by these cases.

The following conclusions seem warranted by the observation of the cases reported:

1. The absence of a history of a trauma or of external evidence of violence in the supra-pubic regions does not exclude traumatic rupture of the bladder.

2. When the rent is large, urine may escape from the catheter in a full stream.

3. When the rent is small and covered by free exudate, urine may likewise escape normally. (Ultzmann.)

4. Peritonitis does not necessarily follow rupture of the bladder.

[1] Abdominal Surgery, 4th ed., p. 752.

[1] Quoted by Ultzmann: Die Krankheiten der Harnblase, 1890, p. 70.

[2] Annals of Surgery, September, 1890.

5. This being so, in a suspected case extreme caution as to asepsis should be observed in catheterization.

6. As an aid in diagnosis the injection of a measured amount of warm sterilized water is in all cases to be tried, the abdomen subjected to careful physical examination before and after the injection, and the amount recovered by the catheter carefully noted. A Barnes dilator in the rectum will aid in lifting the bladder out of the pelvis against the abdominal wall.

7. Hydrogen gas or air may be substituted for water.

8. All injections should be under moderate pressure, as by high pressure an incomplete rupture might easily be converted into a complete one.

9. In all cases of fracture of the pelvic bones rupture of the bladder is to be sought, and *vice versa*, in all cases of rupture of the bladder examination per rectum, etc., must be made for fracture of the pelvis.

10. Extra-peritoneal rupture may be complicated by intra-peritoneal rupture. (See Case VI, in which apparently a spicule of bone made a through-and-through perforation.)

11. Supra-pubic cystotomy or opening of the abdominal cavity in suspected extra-peritoneal rupture is justifiable in order to confirm the diagnosis and to locate the point of rupture, so that drainage can be properly applied.[1]

SOME NOTES UPON URINALYSIS.

BY P. MAX FOSHAY, M.D.,
OF CLEVELAND, OHIO.

IN the course of examining urines I have found that certain data, of which the analyst stands much in need, are not to be met with in any of the works upon urinalysis with which I am conversant, and I have examined, I think, all the manuals in general use. For instance, the average daily amount of total solids in the urine of healthy persons is given by all authors; but a statement as to what range of total solids is compatible with health is made by few, and then not in a satisfactory form. The average amount of solids is usually stated to be 70 grm. a day, but I am of the opinion that this is slightly too high for the average men and women in this country, and think 63 grm. would fall nearer the true average. The specific gravity in health may range from 1.015 to 1.025, the average being 1.020. The quantity of urine passed daily by healthy persons is said to vary from 1300 to 1500 c.c. The Haeser and Neubauer formula for estimating total solids from the specific gravity is sufficiently accurate for clinical purposes. This is executed by multiplying the last two figures of the specific gravity by the factor 2.33, the product of which represents the number of grams of solids in 1000 c.c. of the urine, and must be multiplied by the number of cubic centimeters of the urine under examination, and divided by 1000 in order to obtain the correct amount of solids. Taking this factor and the averages of specific gravity and quantity, we readily arrive at the following results for the health-range of total solids. Employing first the minimum specific gravity and maximum quantity, we have:

$$\frac{2.33 \times 15 \times 1500}{1000} = 52.43 \text{ grm. for the minimum solids.}$$

Using next the maximum specific gravity and minimum quantity, we have:

$$\frac{2.33 \times 25 \times 1200}{1000} = 69.90 \text{ grm. for the maximum solids.}$$

In calculating the maximum and minimum of total solids, I took as a basis the most usual conditions of healthy urine, *i. e.*, maximum quantity associated with minimum specific gravity and *vice versa*. But as there might be cases in which, along with apparent health, the maximum specific gravity is maintained simultaneously with maximum quantity, and *vice versa*, it seemed advisable to determine these widest possible limits of the health-range of total solids, as follows:

$$\frac{2.33 \times 15 \times 1200}{1000} = 41.94 \text{ grm.}$$

$$\frac{2.33 \times 25 \times 1500}{1000} = 87.38 \text{ grm.}[1]$$

In actual examination of urines it will be found that those whose total daily solids persistently approximate to either of these extreme figures represent some deviation from the normal standard of health. Whether a given case is pathologic or not must be determined by noting carefully all the conditions of the patient's environment; whether his diet is liberal or scanty; whether his habits are active or sedentary; the climate and season of the year, and, in addition, sex and weight are important factors in the problem. From my own experience I should say that the first determined limits, viz, from 52.43 to 69.90 grm., are much the safer ones to use in practice.

The ratio which the amount of urea in a sample of urine bears to the amount of total solids has seemed to me to be of some interest and value. Little is

[1] On the Value of Exploratory Laparotomy in Suspected Extra-peritoneal Rupture. *Vide* Cabot: Boston Med. and Surg. Journ., October 15, 1891.

[1] Note the concordance between the average amounts of solids as determined from each of these limits:

$52.43 + 69.90 \div 2 = 61.17$ grm.

$41.94 + 87.38 \div 2 = 64.66$ grm.

An average of these two amounts is 63.42 grm.

said concerning it in the manuals; but I have observed it in an extended series of experiments. It should first be remarked that all my figures are upon the basis of the whole twenty-four hours' urine, and all my examinations, with a few unavoidable exceptions, are made upon the total daily quantity. In estimating urea I use the hypobromite method exclusively, as being, upon the whole, the most satisfactory, and I make a fresh solution of hypobromite of sodium for each and every determination. I use the ureometer devised by Dr. Charles Doremus as the cheapest (for they will get broken), simplest, most readily cleaned, and, in general, the instrument best adapted for use in the physician's office; while at the same time I am confident that the ureometer of Dr. John Marshall is more scientific, more accurate, and better fitted for the use of the chemist. The daily amount of urea excreted in health may range from 20 to 40 grm., according to diet, the average of these figures being 30 grm. I am, however, very much inclined to think that 27 grm. daily is as high an average as the analyst will make in this country. Using our previously-calculated average limits for total solids, we find the limits of the ratio between urea and solids to be as follows:

$\frac{52.43}{20} = 2.6$, or a ratio of urea to solids as 1 : 2.6.

$\frac{69\ 90}{40} = 1.7$, or a ratio of urea to solids as 1 : 1.7.

Here I have employed minimum figures of solids and urea, and *vice versa*, as, of course, we almost invariably find them associated in nature. Taking minimum urea with maximum solids, and *vice versa*, as rarely occurs in health, and never persistently, the ratios will be as follows:[1]

$\frac{69.90}{20} = 3.5$, or a ratio of urea to solids as 1 : 3.5.

$\frac{52.43}{40} = 1.3$, or a ratio of urea to solids as 1 : 1.3.

From these two groups the average ratios will be calculated, as follows:

$2.6 + 1.7 = 4.3 \div 2 = 2.2$ or a ratio as 1 : 2.2

$3.5 + 1.3 = 4.8 \div 2 = 2.4$ or a ratio as 1 : 2.4

Hence we may conclude that the average ratio of urea to solids in healthy urine is as 1 : 2.3, but that there may be a range, dependent wholly upon diet, of from 1 : 1.5 to 1 : 3.0. And I should say from somewhat extended observation upon this point, both in normal and pathologic urines, that a urine in which the ratio of urea to solids remains persistently at either the maximum or minimum figure is not excreted by a person in thoroughly good health. As far as my experiments have gone, the most notable fact to be observed concerning this ratio in the urine of persons suffering from various diseased conditions is its extreme variability from day to day, in this respect differing markedly from the ratios in healthy urines. I should not at present attribute great diagnostic value to this ratio, but in every case I meet it furnishes valuable collateral evidence.[1]

The ordinary volumetric methods of estimating phosphates and chlorids, while they are accurate and not difficult of execution for one who has plenty of time at his disposal, are yet out of reach of the average practitioner of medicine. Yet he would many times profit by the knowledge of the approximate amount of these substances in his patient's urine; so that I have endeavored to improve upon the rough methods of estimation given by most authors. I have not yet proceeded far enough in my experiments to be certain of the value of the method I propose, but, every time that I have checked it by the volumetric methods, it has furnished results sufficiently accurate for the physician's purpose. It is to be borne in mind that the knowledge of the exact amount of chlorids and phosphates in a urine is of no practical value to the physician. If he knows whether these substances are present in increased or decreased quantity, he possesses all the knowledge that he can apply in the present state of our science. The method I use is not new, but I am not aware of its application to the estimation of these salts in urine, though I doubt not it may have been so employed. I venture a hope that some physicians may find the method serviceable.

The necessary reagents are: The same solution of silver nitrate that is used in the volumetric estimation of chlorids (though any dilute solution will answer); a solution of a chlorid (preferably NaCl) of such strength as to represent the average proportion of chlorids in normal urine; and a simi-

[1] Upon the basis of extreme limits of variation of solids the ratios might be figured as follows:

$\frac{41.94}{20} = 2.1$, or a ratio of urea to solids as 1 : 2.1.

$\frac{87.38}{40} = 2.2$, or a ratio of urea to solids, as 1 : 2.2.

The converse $\left(\frac{41.94}{40} = 1.05 \text{ and } \frac{87.38}{20} = 4.4\right)$ is impossible.

[1] For normal urine the following averages are those given in the books for the twenty-four hours' quantity:

Average specific gravity	1.020
" quantity	1350 c.c.
" total solids	70 grm.
" urea	30 "

From this we find an average ratio of urea to solids of 1 : 2.33 $\left(=\frac{70}{30}\right)$. As 63 grm. seems a better figure for average solids, and 27 grm. a more correct average for urea, the corrected ratio will be 1 : 2.3 $\left(=\frac{63}{27}\right)$.

And note that the average amount of total solids calculated from these very figures (quantity 1350 c.c. and specific gravity 1.020) differs from that stated in the table, as follows:

$$\frac{2.33 \times 20 \times 1350}{1000} = 63 \text{ grm.}$$

lar solution of a phosphate (preferably Na_2HPO_4).[1] One-half dozen ordinary stand test-tubes and a graduated pipette constitute the necessary apparatus. The principle of the method is the comparison of the relative bulk of the precipitates formed by adding the silver solution to the normal solutions, with similar precipitates formed by adding the silver solution to the urine. In estimating the chlorids I at present employ 1 c.c. of the sodium chlorid solution diluted to 5 c.c. in a stand-tube with distilled water, and 1 c.c. of the urine to be examined similarly diluted, to which is added one drop of nitric acid to prevent precipitation of the phosphates. Then 1 c.c. of the silver nitrate solution will completely precipitate the chlorid in the standard solution. Add silver solution to the diluted urine until the precipitate no longer forms, and shake both tubes thoroughly. In two or three minutes the comparison of the relative bulk of the precipitates may be made, and will give a fair estimation of the deviation from normal, if there is any, of the chlorids in the urine. This method is very easy of execution, the required solutions keep well, and it furnishes, so far as tested, fairly approximate results.

In roughly determining the phosphates I add 1 c.c. of the sodium phosphate solution to 1 c.c. of the sodium chlorid solution (as the chlorids and phosphates in the urine are necessarily precipitated together) and dilute to 5 c.c. with distilled water. As before, dilute 1 c.c. of urine to 5 c.c., and then add excess of silver solution to each tube, and shake. A mixed precipitate of silver chlorid and silver phosphate falls in each tube, and, as we already know the relative amount of chlorids in the urine, any change from that relation will denote the deviation in amount of phosphates from the normal. I am free to confess that the application of this method to the phosphates is not yet nearly so satisfactory as it is in the case of the chlorids.

Sometimes the analyst receives a sample of urine which is twenty-four hours old, or more, and it would be of great value to know approximately what changes, if any, had taken place in the urine since it was voided, either in specific gravity or amounts of urea and phosphates. The manuals furnish no information upon the point. I have only been able so far to try the effects of time upon the specific gravity and amount of urea, and then not in a sufficiently extended series of experiments to give authoritative results. Taking them for what they are worth, I note the following, and I select one case of each, rather than make an average. On a Sunday the specific gravity of a sample of fresh, warm urine (50 c.c.) was taken and found to be 1.018. When cold it read 1.022, and four days later it was 1.023. The evaporating surface was only three-fourths of an inch in diameter.

In a beaker, three inches in diameter, were placed 200 c.c. of fresh urine. An estimation of urea was made at once, and upon every succeeding day, for seven days. When fresh, the urea amounted to 0.020 grm. in 1 c.c., or 24 grm. in 1200 c.c. On the fourth day it was 0.022 grm. urea to 1 c.c., or 26.40 grm. in 1200 c.c.; and upon the seventh day, 0.0234 grm. in 1 c.c., or 28.08 in the 1200. On the last day the urine was brought to the original bulk by adding distilled water, and then the urea read 0.018 grm. in 1 c.c., or 21.6 grm. in 1200 c.c. The result shows an apparent gain due to evaporation of 4.08 grm. of urea, but a real loss of 2.4 grm. due to decomposition of the urea. It is worthy of note that I find little actual change, except by evaporation, if that is not prevented, in most urines during the first forty-eight hours.

These facts are not sufficiently borne in mind, for I have seen an insurance examiner many times take the specific gravity of a warm, freshly-voided sample of urine and report the result as representative, which it certainly was not.

MASTOID ABSCESS.

BY S. P. SCHROEDER, M.D.,
OF HOYLETON, ILL.

MASTOID inflammation is a complication of suppurative inflammation of the middle ear, but of such gravity and so serious that it might be called a separate disease.

Anatomically the mastoid process lies posterior and external to the petrous portion of the temporal bone. It is composed of cavities, in the healthy state intersected and subdivided by partitions. These cavities open into the tympanic cavity. In suppurative inflammation of the tympanic cavity the inflammatory process may extend into these cells, and once the pyogenic cocci have found entrance and lodgment in these caves, it is easily understood that it will be a hard fight on the part of the physician to get them out of their fortifications. On the inner and posterior side of the mastoid process is found the sigmoid groove, the continuation of the lateral sinus. This groove stands in danger of being injured when the mastoid process is opened.

The causes of suppurative inflammation of the middle ear may be summarized as follows: 1. Cold. 2. Injuries—(*a*) The forcible removal of foreign

bodies, chief of which is impacted cerumen. (*b*) The forcible injection of fluids. 3. The infectious diseases, among which scarlet fever takes first rank. The pathology of mastoid abscess is that of other bone-inflammation. There may be softening, sclerosis, caries, or necrosis.

The accidents, as they may be called, consist in the extension of the inflammatory process to neighboring parts, which occurs in two ways: (*a*) By extension along the vessels and natural openings, and (*b*) by forming a fistulous opening by caries through its bony walls. The inflammation may extend outward, inward, upward, downward, or forward.

When the inflammation extends *outward* it will show itself by edema, redness, and deep tenderness over the mastoid process, and the ear will stand farther from the head than its fellow. If left to open itself, the abscess is slow in its progress, and when it opens the pus is offensive in odor. If the inflammation extends *inward* it will be recognized by symptoms caused by phlebitis, thrombosis, and embolism of that portion of the cranial cavity that is drained by the lateral sinus and the superior and inferior petrosal sinuses. Hence there would be edema of the corresponding side of the face, mastoid prominence, and head, due to the obstructed return-circulation. There may be high fever and vomiting.

If the inflammation extend upward there will be symptoms due to meningitis, as for example, severe headache, not localized, restlessness, fever, vomiting, irregularity of pulse, coma, and death; while, if cerebral abscess should form, I take it the symptoms would be so obscure that they could not be differentiated from those of meningitis, and the diagnosis could only be positively made in the post-mortem room.

If the inflammation extend downward, the pus would gravitate into the retro-maxillary fossa, and from there downward along the cellular plains in connection with the great bloodvessels of the neck. If the inflammation extend forward, an abscess is formed on the posterior wall of the external auditory canal, which, after it opens, leaves a sinus, and from its external opening large granulations spring up resembling polypi.

I shall give the history of a case that had three of these accidents: Periosteal mastoid abscess, extension of the inflammation into the external auditory canal, and very probably cerebral abscess. It also shows the ravages of this affection:

CASE I.—In March, 1889, I was called to see J. McCairy, a farmer, and a native of Ireland, aged seventy years, remarkably stout for his age, who complained of pain in the left ear, which radiated over the corresponding side of the head and face. He had suffered from pain about five days. There was slight fever. Otoscopic inspection revealed a red zone around the attachment of the tympanic membrane, and a red line where the handle of the malleus was located. The membrane was bulging outward, and had lost its luster. There was deep tenderness of the mastoid process. I recommended paracentesis of the tympanic cavity. This he objected to. Two days afterward, however, the patient permitted me to incise the membrane. At this time, however, the external auditory canal was so swollen that it was well-nigh impossible to get a clear view of the membrana tympani. There was some edema over the mastoid prominence, and the ear stood farther from the head than its fellow. I warned him of the gravity of the case, which scared him, and the next I knew he was attended by another physician. After four weeks I was called to take charge of the case again. As soon as I entered the sick-room I observed that the left side of his face was completely paralyzed. The eye of the corresponding side was kept constantly open, even during sleep, contrasting strongly with the facial paralysis due to a central lesion of the cerebrum, in which the upper fibers of the facial nerve are not implicated. The paralysis affected his speech so that it was almost impossible to understand him. It seemed as though the tongue was too large and thick. The soft palate was drawn over to the opposite side; he had difficulty in swallowing, and taste on the corresponding side was deficient. There was a large periosteal abscess over the mastoid eminence, which fluctuated. I opened it, and considerable offensive-smelling pus passed out. On probing I found a fistulous opening in the mastoid process. There was discharge of pus from the ear. After syringing the ear I found large granulations present. On using an angularly bent probe I discovered a fistulous opening on the posterior wall of the external auditory canal, extending into the mastoid process. The late Dr. Henry, of this place, was called in consultation, and with him I saw the case a number of times. The patient grew gradually worse, suffering almost constantly from excruciating pain, except when relieved by large doses of anodynes. He became more paralytic, had more difficulty in swallowing and in speech, and suffered from subjective sensation of heat and cold, till death finally relieved him, six months after the inception of the malady.

Symptoms. When in the course of a suppurative inflammation of the middle ear there is constant tenderness on pressure over the mastoid process, edema and swelling, with the ear pushed out from the head or not, we may suspect mastoid abscess.

The treatment may be divided into general and local. The general treatment includes laxatives and anodynes. Locally may be applied the rubber coil or bags of ice. When heat is desired, a rubber bag filled with hot water may be placed behind the ear, or small sacks filled with heated bran or salt may be used. I would warn against the too common use of injecting hot water into the external auditory

canal, or the application of poultices over the ear, as the moisture and heat increase the pus-formation, and this, as will be readily seen, is dangerous in a closed cavity like the mastoid process. Another mistake often made by general practitioners is the habit of filling the external auditory canal with powdered boric acid when there is discharge from the ear; this will close the fistulous opening or the ruptured drum-membrane, and thereby prevent free drainage. The injection of H_2O_2 has a tendency to thicken the pus and thereby prevent its free exit. The surgeon or specialist will open the cavity or enlarge the already existing fistulous opening which is too small for free drainage.

Two methods of opening the mastoid antrum are in use: One by boring with a drill; the other by chiselling into the cavity with chisel and hammer. In young children, and in those cases in which the bone is softened, the operator may often open into the cavity by pressing well down with a strong knife.

The chief landmarks for the surgeon are the temporal ridge and the external auditory canal. The opening should be made one-half inch below the temporal ridge and one-half inch posteriorly to and parallel with the external auditory canal. The chief risk lies in the danger of injuring the lateral sinus, which may easily occur to a careless operator, but if the foregoing precautions are observed there is little danger.

I will cite here another case in which the cavity was opened, and the case terminated favorably in a very short time.

Case II.—R. A. C., American, aged fifty years; a saloon-keeper, healthy, living only a block from my office; came for me to examine his ear the 1st of April, 1892, when he complained of severe pain on the right side of the head, radiating from the ear in all directions. There was partial deafness and tinnitus. On inspecting the affected ear, I found all the symptoms of suppurative inflammation of the middle ear. He was treated in the usual way. The case progressed rather slowly, but I hoped for a favorable termination. He was never confined to his bed. He had greatly improved three weeks after the first treatment. About this time he went to Centralia, exposing himself, and on his way home he got wet in a cold April shower. After he came home he suffered with a chill, and in a few days all the ear-symptoms took on an acute exacerbation. The pain was very severe, deep tenderness over the mastoid process developed simultaneously, and a day later there was swelling and edema of the mastoid prominence. I recommended opening of the abscess, to which the patient consented. On the 24th of April, with the assistance of Drs. Carter, of Nashville, and Beckmeyer, of Addieville, we proceeded to open the abscess. The head for a short distance around the process was shaved and thoroughly cleansed with soap and water, and then with an antiseptic solution. A crescent-shaped incision, posterior to the ear and with its concavity toward the ear, was made, and then a cross incision at right angles from the first was made, extending backward. The pericranium was pushed back and the bone examined to see whether or not a softened place could be found. As we could not discover this, an opening was bored with the triangular centerpiece of a three-quarter-inch Galt trephine. Great care was taken in directing the trephine-point, so that it was parallel with the external auditory canal and one-half inch below the temporal ridge. After boring down fully three-eighths of an inch, dark blood oozed out, and it was thought best not to bore any deeper.

This patient expressed himself perfectly free from pain after he recovered from the anesthetic, and made a very rapid and uninterrupted recovery. The wound was not closed, but dressed and treated open, in order that drainage might be free. The objection to the boring is, that the operator has to work in the dark and does not know when he has entered the mastoid antrum; for this reason I think that the chiselling procedure will supersede the boring.

OBSERVATIONS ON THE TREATMENT OF ASCITES BY FARADIZATION OF THE ABDOMEN.

BY ROBERTS BARTHOLOW, M.D., LL.D.,
OF PHILADELPHIA.

On first view it would hardly be credited that an effusion into the peritoneal cavity could be made to disappear by faradization of the abdominal muscles. Nevertheless, many cases have been reported, and I have had personal experience of two instances. The most recent paper on this topic that has fallen under my observation is that of Prof. Dr. Glax,[1] who reports on some new cases supplementing a former paper, and at the same time giving an account of the literature of the subject so far as it exists.

Although, as we shall presently show, ascites of widely different origin can be successfully treated by electricity, there are some contra-indications to the use of this agent. Not all cases are suitable for the applications of a remedy causing such violent concussion of the abdominal contents. Cases of acute or subacute peritonitis, when general soreness and tenderness accompany the effusion; or when a general peritonitis succeeds to a local inflammation —such as typhlitis—and ascites results,—these conditions are unfavorable for faradization. However, after all acute symptoms have subsided, and tenderness has disappeared, faradism may be resorted to, for cases of this character have been successfully treated by faradism.

The ideal case of ascites for electric treatment is that of complete distention of the abdomen caused by portal obstruction of a remediable character. Usually, however, the case is one of cirrhosis due to

[1] Centralblatt für die gesammte Therapie, November, 1892.

the alcohol-habit. In such an example the ultimate result depends on two factors: on the amount of hepatic substance remaining in a condition to functionate; on the ability of the patient to free himself from the alcohol-habit. It is understood that every organ of the body contains an excess of structural material above the needs of its function, and hence may lose some parts without becoming unequal to its place in the organism. Cases of ascites caused by cirrhosis getting permanently well under faradism may be of such kind. The last case in my charge was one of portal obstruction caused by alcoholic excess, the patient indulging enormously in champagne-drinking. Daily applications of the interrupted current to the abdominal muscles caused the fluid to disappear in four weeks, with, apparently, complete restoration of the general health. Of course, permanence of the cure depends on the patient refraining from further indulgence. The ascites of cirrhosis has been successfully treated by Solfanelli,[1] the original proposer of the faradic method, and by Alvarenga,[2] who appears to have been the second advocate of this plan. Ascites of chronic nephritis has been reported as cured by Muret,[3] whose experience was gained at Strasbourg, in Kussmaul's clinic, by Erb,[4] and others. Glax[5] refers to three cases of mitral insufficiency, and one of chronic peritonitis, in which the effusion was absorbed; and Muret cites two cases due to splenic tumor, and one of chronic tuberculous peritonitis, in addition to those already given, the result being the same—*i. e.*, disappearance of the effusion.

The explanations of the curative action of faradism in cases of ascites differ somewhat. It is urged by Solfanelli, by Segrist, and by Glax that strong muscular contractions be induced. Such advice does not necessarily imply that the effects of the current are supposed to be mechanical only. Erb maintains that reflex and catalytic actions, rather than mechanical, explain the absorption of the fluid. By Muret, Glax, and others the effect is attributed to the strongly contracting muscles acting on the contents of the cavity, but especially to the impression on the peripheral nerves reflected over the renal nervous apparatus, and to the reflex action proceeding through the medulla oblongata to the vasomotor system, thus affecting the vascular tension. These remote effects of abdominal faradization have been experimentally studied by Glax, who likens the action of faradic electricity applied to the epigastric region to the "crushing-blow experiment" of Goltz. Indeed, Busch[6] reports a case of syncope induced by the faradic current applied to the epigastrium.

Some late investigations into the effects of abdominal massage throw light on this subject—for a certain similarity exists between the mechanical and reflex effects of massage and the mechanical and dynamic actions of electricity. Eltz,[1] following up the investigations of Riebmayer and Nothnagel, confirms the conclusions of his predecessors, and ascertains that abdominal massage increases the absorption of intraperitoneal and intestinal exudates and the flow of urine. The effects of abdominal massage on the renal secretion have been studied especially by Hirschberg,[2] who finds that the amount of urine discharged is greatly increased, and this is a constant phenomenon. It is undoubtedly the case that massage of the abdomen acts mechanically on the organs within, and especially on the intestinal contents. I have known a case of intestinal obstruction, which resisted the best efforts of several physicians, to yield in an hour to the manipulations of a masseur, who was at the same time a practitioner of the black art.

These facts respecting abdominal massage rather indicate that the effects of faradism, in causing the absorption of the fluid in ascites, are more reflex than mechanical—more the increased action of the absorbent vessels and of the kidneys than the mechanical impact of the contracting muscles. The catalytic effects of the current on which Erb insists constitute a mysterious property—more an attribute of the galvanic than of the faradic form of electricity, if for no other reason that the galvanic is far more diffusible.

As the vasomotor and trophic actions are more affected by the galvanic current, I have sometimes resorted to the combined galvano-faradic, interrupted from sixty to eighty times per minute. There is another mode of applying the two currents simultaneously: by maintaining central galvanization, whilst the faradic is used by the ordinary arrangement of electrodes. Central galvanization may be accomplished as follows: by placing one electrode—the anode—over the seventh cervical vertebra, and the other—the kathode—on the epigastrium, and thus permitting a stabile descending current to flow steadily for the required time. With such an arrangement of the electrodes, the great central organs of the nervous system of animal and organic life are included within the circuit. At the same time that the central galvanization is proceeding, static electricity may be used instead of the faradic. This form of electric action is capable of more powerful muscular effects, with less of discomfort than faradic electricity. As Solfanelli, Alvarenga, Glax,

[1] The Practioner, supra.
[2] Bulletin Général de Thérapeutique, vol. cxvii, p. 259.

and Muret[1] insist on the necessity for strong muscular contractions, it may be better to make use of static electricity, and I have done so, as just stated, in the last case under my charge—with apparent advantage, but I am not prepared to say that it should be applied exclusively or in part in any case. I have employed the Toepler-Holtz machine, which is arranged in an air-tight glass case, the discharging rods outside. To procure a sufficient amount of action, the rods are so adjusted as to permit sparks to pass at intervals of from sixty to one hundred per minute, and the current is tapped by connecting the electrode wires with the inner and outer parts of the Leyden jars.

Either of two plans may be pursued in applying the faradic current: one electrode placed on the upper dorsal vertebra, and the other moved over the abdominal wall, so that each group of muscles is acted on, or both electrodes held in one hand, according to the method of Duchenne, and each group of muscles made to contract several times before passing on to the next. Fatigue of the muscles should be avoided, for this indicates that the applications have been too protracted or too strong. The *séances* should not exceed fifteen minutes in duration, and they need not be more frequent than once a day. In some of the reported cases the faradic applications have been made two and three times a day, and with increased rate of improvement; but, as a rule, once a day suffices.

The improvement noted begins immediately, and an actual diminution in the girth of the abdomen is observed from a single application. The more fully distended the abdomen the more promptly does absorption occur, but the rate of absorption lessens with the diminishing fluid.

THE USE OF THE CURETTE IN ABORTION.

BY R. E. SKEEL, M.D.,
OF CLEVELAND, OHIO.

No one who forms the habit of examining the pelvic organs of all married women applying to him for relief from general nervous symptoms, as well as local evidence of intra-pelvic disease, can fail to be struck by the great number of cases of endometritis, salpingitis, and old pelvic exudates, dating from a miscarriage or abortion. In many of these cases the patient either did not employ a physician, or did not summon him until serious symptoms, such as profuse hemorrhage, foul discharge, or severe pain, had occurred. In other cases the physician was called, but resorted to the old temporizing measures, because the patient objected to active treatment, or because he did not believe it indicated. Nearly all, if not all, of these serious sequelæ might be avoided by proper treatment with aseptic or antiseptic precautions. Too often the medical attendant is inclined to relieve the mind of his patient by assuring her that she will be all right, trusting to luck to avoid any immediately serious consequences, and hoping that the remote ones will not be properly traced.

The ignorance of the laity is often a bar to proper treatment, and we should do all in our power to educate them to recognize that an abortion is not a simple matter, but that, owing to frequent retention of secundines and, before the third month, the decidua vera, it is extremely likely to be followed by serious disorders.

The use of the curette is sometimes condemned in all cases in which membranes or placentæ are retained, unless serious symptoms supervene, and this objection is based on the theory that there is danger of infection, and that all shreds of decidua cannot be removed in this manner. Theoretically this does not appear to me to be true, and practical results prove that the immediate removal of all retained products of conception, and, before the third month, curetting to remove the decidua vera, is followed by results as nearly perfect as can be asked for. If we can fearlessly enter the uterine cavity and curette for endometritis, we can as safely do so for the removal of foreign matter retained there, and with as little danger of infection. Further, it has been proved that the cervical canal contains microbes that under ordinary circumstances are harmless, but which readily become virulent in the presence of dead animal matter. That all shreds of decidua can be removed I am certain, from an experience in a considerable number of cases.

Clinically, three classes of cases present themselves to us, leaving out of consideration those in which prophylactic measures may prove successful:

1. Cases of inevitable abortion.
2. Those in which the ovum, in whole or in part, has recently come away.
3. Cases in which, after the lapse of some time, hemorrhage, or decomposition, or pelvic peritonitis, has occurred.

In the first class of cases we meet with a few in which the hemorrhage is very profuse before dilatation has occurred, and here the great majority of authorities agree that immediate dilatation is required; with a careful scooping out of the ovum either with the finger or ovum-forceps. In addition to this, as we are obliged to enter the uterine cavity, it would seem advisable to use the curette in all cases occurring before the third month, for the purpose of removing the hypertrophied mucous membrane forming the decidua vera. If this is not curetted it will generally come away in shreds,

[1] The Practitioner, vol. xli. p. 448.

and from the entrance of air it has abundant opportunity to putrefy and set up septic trouble.

In cases with only moderate bleeding the *antiseptic* tampon, properly used, will control the hemorrhage, and at the same time secure rapid dilatation and frequently expulsion of the ovum. If this comes away entirely, it may be debatable as to what is the best course to pursue. The vast majority of cases have no further trouble, but the thickened decidua is certainly a foreign body, and it would seem best to proceed with a thorough scraping. If the ovum is not expelled after a few hours, it should then be removed by the finger and curette, as nothing is to be gained by further delay.

In the second class of cases, unless we have seen the ovum and are positive that it is entire, it is far better to thoroughly but gently scrape over the surface with the Récamier curette, the danger from this procedure being much less than that of retention of matter that so readily becomes septic.

The cessation of pain and hemorrhage is not positive evidence of the complete expulsion of the uterine contents, although the converse is undoubtedly true. In those cases in which hemorrhage persists or the lochia are offensive, no one will object to the removal of the retained matter, and here again the curette is the only instrument at all effective, removing, as it does, all shreds and attached portions of membrane, and leaving no nidus to favor the development of bacteria, to result in the production of a purulent or hemorrhagic inflammation of the endometrium in later years. When pelvic peritonitis has occurred, the same principles should apply, but the treatment, advocated by Polk, of subsequent drainage certainly looks feasible. In this class of cases there is not the immediate improvement which follows when a pure sapremia exists, but the primary infecting center should none the less be removed.

This operation can be safely performed with lay assistance only, if professional help is not obtainable. An anesthetic is rarely necessary.

A vaginal douche should first be given of 1 : 3000 hot bichlorid solution. The Kelly rubber pan or some similar receptacle is of great assistance. If the physician is obliged to do the operation unaided, the patient is placed in the lithotomy position, and the bivalve speculum, well sterilized, is introduced. The cervix is steadied with a tenaculum or tenaculum-forceps, and the sterilized sound is introduced to ascertain the size, depth, and position of the uterus.

A Récamier curette, the large end of which is dulled by rubbing on a whetstone, or by filing, is introduced and the entire uterine cavity is thoroughly gone over without any great amount of force. Sterilized hot water or hot bichlorid solution, 1 : 10,000, is now used to wash out the débris, and, when no more comes away by washing, the uterine wall is again gently scraped, to ascertain whether anything still remains attached to it. If nothing more is removed, the uterus is again thoroughly washed out, a final vaginal douche is given, and the antiseptic pad applied over the vulva. Of course, perforation of the uterus is possible; but this ought never to happen if the curette is handled gently and no undue force is used.

I am aware that the principles urged in the foregoing are in the main those advocated by Hirst; but it is the writer's object to emphasize the connection existing between the retained products of conception and infection followed by acute or chronic endometritis, and to urge the use of the curette more generally to avoid these disastrous after-effects.

Like the uterine sound, the curette is capable in careless hands of doing great damage, but properly used it is also, like that instrument, invaluable.

ALBUMOSE.

By R. W. FISHER, Phi.G., M.D.,
of Salt Lake City, Utah.

The presence of albumose in the urine has not received the attention it deserves; in the first place, because of its rarity, and in the second, because it seems difficult to associate the substance with any particular pathologic condition.

Nearly all writers on the chemistry of the urine either quote from some other work or give it some new name, till the subject is much bewildered and the chemical reactions are not well understood.

That this form of albumin is much oftener present than recognized, is, I am quite sure, owing to methods used. The routine method in general use, as is well known, is to add acetic acid to the urine and boil. If this gives no reaction it is taken as final. As the reactions given further on will show, this would fail to demonstrate the presence of albumose.

Bence Jones was the first to write on this subject. He found albumose in the urine in a case of molities ossium, and gave it the name of hydrated deutroxid of albumin. Kuhne also describes a case and gives it the name of hemialbumose. Da Costa describes a number of kinds of albumin, and to this one gives the name albumose, which I have adopted. Roberts does not record any cases but says it is considered identical with the pro-peptone of Schmidt-Mulhein, and with the peptone of Meissner.

Peptone is very frequently found in the urine in cases of rheumatism or when the exudation is being absorbed in pleurisy or pneumonia, and should be carefully excluded.

The best test for peptone is the overlaying test

with Fehling's solution, which gives the rose-colored zone; but if albumin is present the color is purple. Potassium ferrocyanid and acetic acid give a precipitate with albumose, but not with peptone.

All the writers on this subject have made the same mistake in stating that albumose is not precipitated by heat. If the urine is very acid, or if there has been any acid added, there will not be any precipitate on heating. Holland, in speaking of this, called it acid albumin.

In making a test, one should be sure the urine is not too acid; otherwise there will be no precipitate and this form of albumin will escape notice. There must be some change in the kidneys, as in all the cases I have seen there were hyaline casts.

My attention has only recently been called to this subject, and I have had no opportunity to examine the kidneys post-mortem. In my experience the substance has always been found in some diseased condition of the bones.

Whether there is any connection between the two conditions, I am not prepared to state at present.

The following are the tests for albumose. It is precipitated by alcohol, carbolic acid, nitric acid, chromic acid, mercuric chlorid, tannic acid, picric acid, and metaphosphoric acid. If the urine be first acidulated with acetic acid, albumose will be precipitated by potassium ferrocyanid, potassio-mercuric iodid, sodium chlorid, magnesium sulphate. All these precipitates are dissolved by heat.

The best method for separating the proteids is given by Da Costa. Saturate the urine with ammonium sulphate, which will precipitate ovalbumin, serum-albumin, paraglobulin; collect on a filter and test the filtrate for peptone. Dissolve the precipitate in distilled water and acetic acid, add ether, and if ovalbumin it will be coagulated. To the solution add magnesium sulphate and acetic acid, and paraglobulin and albumose are precipitated. Da Costa says magnesium sulphate will precipitate albumose, but unless acetic acid be added there will be no precipitate If the precipitate will dissolve on heating, it is albumose; if not, is paraglobulin.

The mistakes that are generally made are in confounding albumose with peptone, mucin, and paraglobulin, but with a little care and applying the well-known tests these can be excluded.

Aneurism of a Sinus of Valsalva.—At a meeting of the Medical Society of Hamburg, SIMMONDS (*Deutsche medicin. Wochenschr.*, No. 51, 1892, p. 1171) presented an aneurism of a sinus of Valsalva that had pushed a leaflet of the pulmonary valve before it, and had ruptured into the pulmonary artery. The aorta displayed the remains of a previous endocarditis, two leaflets being agglutinated. The specimen was obtained from the body of a man, forty-two years old, who had died with symptoms of profound pulmonary edema.

ORIGINAL LECTURE.

PROLAPSUS UTERI.

Delivered at the Philadelphia Hospital, October 22, 1892.

BY E. E. MONTGOMERY, M.D.,
PROFESSOR OF GYNECOLOGY, JEFFERSON MEDICAL COLLEGE; OBSTETRICIAN, PHILADELPHIA HOSPITAL; GYNECOLOGIST TO ST. JOSEPH'S HOSPITAL.

I BRING before you to-day a patient, fifty-three years old, who presents a history of having suffered from so much pain in conjunction with a scanty menstrual flow as to be confined to bed during the entire period. Some years ago she noticed a settling down of the uterus, when she suffered from disordered menstruation, pain and tenderness in the pelvis and a profuse discharge. She has had two children at term, and two miscarriages, one at the second, and the other at the fourth month. In both of her confinements it was necessary to use instruments, and she was torn; a prolapse of the uterus took place after the birth of the first child, twenty years ago. She has done heavy work for many years, and in addition has suffered from troublesome cough and from constipation. She gives no history of abdominal enlargement. The measurements between the spines of the ilia are 27 cm., between the crests 29; Baudelocque's diameter is 18. She underwent an operation two years ago in the Presbyterian Hospital, when a portion of the uterus was removed.

I have not as yet had an opportunity to examine the woman, and bring her before you to-day for that purpose. As I separate the vulva, you notice there is a slight protrusion of the posterior wall of the vagina, which is known as a rectocele; if situated in the anterior segment, or anterior wall of the vagina, it would be called a cystocele. As I introduce my finger I find it comes in contact with the bar of a pessary, and it is probably due to the presence of this instrument that there is no greater displacement. As I withdraw it I find that it was situated wrong side up. This may have resulted, however, from its having been displaced in walking. As I introduce my finger into the vagina I find the uterus to be flush with it. The uterus is small and the vagina completely relaxed. If the woman engaged in slight exertion and straining, the protrusion of the vagina would be greater than it is.

This pessary is known as a retroversion pessary. In a patient like this, with the cervix entirely gone, it has no effect other than to distend the vagina and prevent the vaginal walls from being relaxed. In order to sustain the uterus when retroverted there must be a sufficient amount of the cervix projecting into the vagina for the pessary to act upon and drag backward. The pessary does not serve as a support for the fundus of the organ, but as it draws back the posterior fornix of the vagina, the traction is exerted upon the cervix, which is drawn backward and upward, the other end of the lever—the fundus—being tilted forward.

In introducing the pessary you separate the vulva with the left hand; then, taking the pessary between the thumb and the forefinger of the other hand, its posterior bar is held parallel with the axis of the vulva, and is pressed against the posterior commissure of the perineum, pushing this backward until one-half of the

pessary has entered the vagina. It is then rotated, and, with the finger placed against the posterior bar, the latter is carried behind the cervix into the posterior fornix.

The next patient is a woman, eighty years old, who enjoyed perfect health until three years ago. Her menstrual life was regular and painless. She has had four children at term and two miscarriages, the latter occurring at the beginning and end of her childbearing life. Her occupation was that of a cook, necessitating her being much upon her feet. She has always suffered from constipation; her labors were natural and easy. She never suffered with violent cough, nor has she had any abdominal enlargement.

This patient presents a most interesting condition. As we separate the limbs and expose the external genitals you see the entire uterus, covered by the vagina, projecting from the vulva. A portion of the bladder is situated in the anterior portion of this tumor; the external os and the cervix, as you see, have undergone some ulceration. This patient differs from the preceding one in presenting the condition that is known as procidentia, the latter term being only applicable to those cases in which the entire uterus makes its exit from the genital canal. Procidentia differs from the term prolapsus in being more definite and applicable only to those cases in which the prolapse is complete.

In the study of prolapsus and procidentia, it is well to consider for a moment the relation of the uterus in its normal position and the forces that conspire to maintain it. The organ is situated, as you remember, between the rectum posteriorly and the bladder in front; it is situated in the upper part of the vagina, projecting into it to a limited degree, the projecting portion being known as the vaginal portion of the cervix. The uterus does not occupy a fixed position. It may vary to a considerable degree from one position, and the change still not be a pathologic one. Thus, it may be pushed forward by distention of the rectum, or backward by distention of the bladder. It may be displaced downward by intra-abdominal pressure or by traction upon the cervix, to again resume its former position when the displacing influence is removed.

It is a point of interest to consider the forces that retain the uterus in its normal position. There has been much discussion upon what these are, some claiming that the uterus is set on top of the vagina like a cork in a bottle; so long as the vagina keeps its normal position the uterus is retained in place. Others attribute its support to the ligaments, notably the utero-sacral; when these ligaments lose their natural resiliency they no longer resist the displacement of the uterus, and are gradually elongated or atrophied until procidentia takes place. Some attribute the maintenance of the organ in place to the suction of the peritoneal cavity; some to the peritoneum. The truth is, it is not any one of these forces, but all combined.

In considering the ligaments of the uterus, it is well to remember that they have, running out in their folds, muscular structure from the superficial and middle layers of the uterus, and it is from the influence of this structure that the organ retains its normal position. To determine this fact, it is only necessary to drag upon the uterus, when upon removing the traction the organ will be found to resume its normal position. You will find the vagina represented in some text-books upon anatomy as distended. Such a condition, however, is abnormal, as the anterior and posterior surfaces lie in contact. The vagina lies at an angle of 60° with the horizon, and the uterus, with the bladder empty, lies with its axis at an angle of about 45° with that of the vagina, and the displacement of the uterus into and its exit from the vagina constitute a hernia just as much as would the emergence of any of the abdominal viscera through the femoral or inguinal canal.

One of the first tendencies to displacement downward is manifested in the change of relation of the axis of the uterus with that of the vagina. When the uterus becomes displaced backward, so that its axis is parallel to, or continuous with, that of the vagina, the patient suffers from increased abdominal pressure upon the fundus and back part of the uterus, bringing it down into the vagina as a wedge. The subsequent displacement of the organ is much more rapid, depending, of course, upon the degree of resiliency and resistance of the remaining structures. This tendency to displacement may be aggravated by two conditions; either a want of support in the genital canal, resulting from lesions of parturition, or increased weight and intra-abdominal pressure on the part of the uterus itself, or of any growths about it. When these two forces conspire together, the displacement is much more rapid. The weight of the uterus will be increased by a state of chronic inflammation or subinvolution from the presence of fibroid tumors in its walls. Intra-abdominal pressure is increased independently of the uterus by the presence of growths in the abdominal cavity, such as ovarian tumors, tumors of the omentum, liver and spleen, and from tight lacing.

The most frequent cause of displacement is a laceration of the perineum and of the vagina, taking place during labor. The effect of these lesions is dependent somewhat upon their extent. When the entire perineum is torn through to the sphincter ani there is at once a want of support of the anterior segment of the vagina, and the bladder becoming filled, the uterus resting upon it leads sooner or later to sagging down of this organ and the formation of what is known as cystocele. If the laceration has been extensive there will also be a turning out of the posterior wall of the vagina, giving rise to what is known as rectocele. The traction of the walls of the vagina upon the cervix leads to its being drawn lower down, and more nearly in the axis of the vagina; and in this way the fundus of the organ is tilted backward.

There are varying degrees of the displacement; thus, when the uterus has settled down to the vulva or rests upon it, the condition is known as prolapse of the first degree; when a portion of the uterus protrudes, the condition is known as the prolapse of the second degree; and when the entire organ has emerged from the vagina, the condition is known as prolapse of the third degree, or procidentia.

In some cases the traction of the walls of the vagina upon the cervix is not sufficient to lead to the displacement of the uterus. By dragging upon the cervix the heavy walls exert traction upon it, and if the fundus of the uterus be fixed by a normal, healthy condition of the ligaments, or by inflammatory adhesions, the supra-

vaginal portion of the cervix becomes elongated, until the cervix presents a cord-like attachment connecting it with the fundus of the uterus above. This condition is known as hypertrophic elongation of the cervix, and is one that must be recognized, as failure so to do will render the attendant unable to cope with the difficulty. A violent cough or obstinate constipation tends to aggravate the rapidity of the displacement. The occurrence of prolapsus is not an indication that the woman has borne children, as we not infrequently find women who, from defective muscular development, from obstinate constipation or other causes, may suffer from prolapsus of the uterus. Some years ago I saw a patient in whom prolapsus occurred from intra-abdominal pressure, during dancing. Examination disclosed the fact that she had an ovarian tumor, which had pushed itself down into the pelvis, and had consequently displaced the uterus.

Patients suffering from beginning prolapsus will complain of sensations of weight or dragging, as if everything was about to fall out. This is increased by muscular effort, straining, lifting, and by locomotion. There is more or less irritation of the rectum, possibly increasing the tendency to constipation. There is a sensation of discomfort in the bladder, increased by pressure. The patient is annoyed by frequent micturition. The vesical distress is greatly increased as the prolapse progresses. A portion of the bladder-wall becomes situated below the level of the urethra, so that the bladder is never completely emptied unless the pouch is pushed up. This is attended with decomposition of the urine in the cul-de-sac, and not infrequently with a deposit of calcareous material, which may result in the formation of a large calculus.

The diagnosis of prolapsus can be readily made by an examination of the protruding mass. If we find the protrusion to be situated on the anterior wall of the vagina, while the finger passes into the vaginal canal posteriorly to this, we recognize that we have to deal with a cystocele. On the contrary, if the finger passes anteriorly to the protruding mass, this is evidently a rectocele. These conditions may be present independently of the displacement of the uterus. When the tumor is situated centrally and is covered by the vagina on all sides, with an opening in the center of the protruding mass, we recognize it as a prolapse of the uterus. The protruding mass should, however, be carefully examined to see whether it includes the entire uterus or whether the cervix or fundus has been drawn out as already suggested.

How shall we treat these displacements? The earlier writers were in the habit of regarding the uterus as a sentient body, which could be frightened back into its normal position by being brought into contact with disagreeable objects. Soranus criticises his colleagues or competitors for placing the woman head downward for twenty-four hours with a view of correcting the displacement. The first consideration in treatment is to replace the organ in its normal position. This is ordinarily accomplished with but little difficulty. Tilting up the fundus of the uterus, bringing it into the canal and pushing upon the uterus, in this way inverting the vagina, the organ is replaced in its proper position. Occasionally the congestion of the uterus and tissues, resulting from the displacement, may have been of such a character as to lead to enlargement of the organ to such a degree as to prevent its being readily pushed back. In such cases it may be necessary to apply an Esmarch bandage to the surface of the tumor, thus pressing the blood out of it before it can be returned.

The protruding mass, exposed as it is to contact with the urine, to friction from the limbs and clothing, soiled with the discharges from the rectum, is not infrequently the seat of extensive ulceration. The tendency to ulceration is enhanced by the congestion of the organ and the consequently lowered vitality. When the uterus has been displaced for a length of time; when intestinal coils have followed it and have become adherent in abnormal situations, the replacement of the uterus may be impossible.

Having replaced the uterus, we have now to consider the manner in which its normal position is retained. This may be accomplished in two ways: by the use of pessaries or by a plastic operation. A great variety of pessaries have been introduced for this purpose. They may be divided into two classes: those without and those with external support. Those of the former class rest upon the posterior segment of the vagina and maintain the uterus in its normal position. When the vagina is large and roomy, or the uterus has been frequently displaced, or the displacement has existed for a considerable length of time, the retention of a pessary may be attended with difficulty.

The use of pessaries is not infrequently attended with discomfort. If the vaginal canal has been extensively injured, the pessary finds no point of support, and is readily pushed down and out. If the pessary is too large, and makes undue pressure upon the vaginal walls, it should be removed. From the secretions of the vagina calcareous material is not infrequently deposited upon the pessary, producing a roughening of its surface, which results in ulceration of the parts irritated by it. Wearing a pessary is at best attended with a good deal of discomfort, so that not infrequently a patient herself is willing to submit to any operation that will enable her to forego the necessity of wearing such an instrument.

In the patient before us, eighty years of age, no operation would be justifiable; her tenure of life is so short, the probability of successful result so slight, that it would not be wise to undertake an operation. We would suggest that the vagina be packed two or three times a week with iodoform-gauze and the uterus in this way held up. The incorporation of glycerin with the gauze will be of advantage. A great variety of plastic operations have been done upon the vagina and its outlet. Thus, the perineum has been denuded and a skin-flap made; in other cases a denudation has been practised upon the posterior wall of the vagina, extending up toward the uterus; or again, denudation has been done upon the anterior wall, in the form of a triangle or of an ellipse, in an oval denudation, and so on. In ordinary cases, probably as good a method of procedure would be to denude the surface upon either side of the urethra, on the anterior wall of the vagina, and suture this, as recommended by Skene. This may be done with buried catgut sutures. The posterior wall of the vagina may be operated upon by making a triangular incision upon its posterior surface down to the vulvo-vaginal communica-

tion, and then freshening the perineum below and introducing sutures in such a way that each drawing of a separate suture will result in lifting up the posterior wall of the vagina against the anterior. This imitates Nature's method.

An operation introduced by Le Fort some years ago consists in denuding a surface of about four-fifths of an inch on the anterior wall of the vagina with a corresponding one on the posterior wall, and bringing these two raw surfaces together by means of sutures in such a way that union takes place; the uterus is supported on the vaginal septum and the vagina is divided into two canals. This operation is one that is applicable after the menopause, but not prior to this, as we can readily understand that the occurrence of pregnancy under such a condition would be likely to result in serious laceration. In the majority of cases the operation suggested by Martin is probably the most effective. This consists in amputation of the cervix, thus securing a depletion of the uterus; second, the narrowing of the anterior wall of the vagina; and third, narrowing of the posterior wall and enlarging the perineum.

CLINICAL MEMORANDUM.

A CASE OF PUERPERAL ECLAMPSIA AT THE SEVENTH MONTH; WITH A FEW THOUGHTS AS TO TREATMENT FROM PRACTICAL EXPERIENCE.[1]

BY DOUGLAS AYRES, M.D.,
OF FORT PLAIN, N. Y.

PUERPERAL eclampsia, threatening, as it always does, the life of the mother, cannot fail to seriously disturb the mind of any practitioner of medicine, however extensive may have been his experience. The mother, if she be in labor, suddenly complaining of pain in the head, perhaps of some derangement of vision, epigastric pain, dyspnea, etc., soon has a convulsive seizure, which, if once seen, can never be mistaken. The staring eyes, the wonderfully rapid contracture of the facial muscles, the rolling eyeballs, and the contracture of the muscles of the neck, drawing the face to the extreme right or left, with the livid appearance and protruded tongue, and saliva forced from the angles of the mouth, take away almost every semblance of "the human form divine." This, together with the contracture of the muscles of the extremities as well, is a condition which has doubtless been witnessed by every physician within hearing of my voice; and all who have seen it will acknowledge that it is one of the most serious conditions that we are called upon to treat; one in which the prognosis is always grave; one that requires early and most vigorous treatment. We can congratulate ourselves, perhaps, upon the fact that it is not of frequent occurrence, as various statistics prove that it occurs but once in about five hundred pregnancies.

I have selected a case that occurred in my practice during the past year for this report, on account of its occurrence at the seventh month of utero-gestation, thereby offering serious complications. It is not my purpose at this time to discuss the etiology of eclampsia, further than to say that it may be of uremic, reflex, or apoplectic origin; that, while albumin in the urine may be a very constant attendant, cases may occur without any, or scarcely any, being present. Great excito-motor irritability may act reflexly and produce uremic attacks, as irritation of the gravid uterus; but cases that can be traced purely to these causes, I judge, from my reading and practical experience, to be very rare. Those of apoplectic origin are undoubtedly the most fatal. I would say, in this connection, that I believe that those investigators who think that the greater proportion of these cases have their origin in uremia are correct; that is, uremia in a general sense, including any or all of the constituents of the urine that may be retained as the result of imperfect action of the kidneys, together with marked increase of arterial tension.

CASE.—The husband of Mrs. F. H. called at my office July 5, 1891, to inform me that she was seven months advanced in a second pregnancy; that there was some puffiness of the face, and some edema of the lower limbs. I requested a specimen of her urine of the twenty-four hours, which I examined with reference to the presence of albumin, of which I found a large amount. The quantity of urine passed we estimated to be about one-third less than the normal average, or about thirty-four ounces. The usual treatment was advised: mental quietude, milk-diet, with iron tonics and mild laxatives.

About 4 P.M. of July 9th (four days after the first call) I was again hastily summoned to attend her. Her mother gave me the following history: She had felt as well as usual on that day, until the afternoon, when she had complained of some pain in the head and had gone into another room to lie down upon a couch. Shortly afterward the mother heard a sound as of something falling, and hastily went into the room, where she found her daughter lying upon the floor in an unconscious condition. There were slight convulsive movements. She recovered consciousness in a short time, when they placed her upon the couch, where she lay quietly, asking some questions with regard to what had happened, but in a somewhat dazed manner.

When I arrived, she seemed perfectly conscious of her surroundings, and answered intelligently the few questions that I asked her. I remembered that I had attended her in confinement eleven years before, and that immediately after the birth of the child she had an eclamptic convulsion, for the relief of which I bled her very freely (nearly thirty ounces), which seemed only sufficient to reduce the force and volume of the pulse, after which she rallied; and very luckily there was no recurrence.

I found her face puffy, and the lower extremities quite edematous. She was thirty-six years old, a person of full habit, weighing perhaps one hundred and forty or fifty pounds. The kidneys had acted about as usual (as well as the family could judge) for the past few days; if there was any change there was a little falling off in the amount of urine passed, from our previous estimate. I found a full, strong pulse, flushed face, and heat of head. I ordered cold applications to the head, and, as the bowels had not acted as freely as desirable, also a stimulating enema, which met with a fair response; and gave immediately afterward a full dose of calomel and jalap. She was soon seized with a severe convulsion. I immediately opened a vein, with a good free opening, from

[1] Read at the meeting of the New York State Medical Association, November, 1892.

which I allowed the blood to flow, until its effect was very perceptible upon the pulse (which required the loss of nearly twenty-five ounces), when she slowly returned to consciousness. I then made a vaginal examination, and found the os somewhat softened and dilatable.

There were at this time marked labor-pains. Making use of the fingers as my dilators, I began slowly and carefully to dilate, and found that the parts yielded very satisfactorily. When the efforts of the uterus, which had now somewhat increased, had pressed the head well down in the os, I administered three-quarters of a dram of fluid extract of ergot, with one-third of a grain of morphine, and shortly after applied the forceps, making gentle traction with each expulsive pain; and in a short time succeeded in delivering a dead child. The uterus was well and carefully kneaded, and within one-half or three-quarters of an hour the placenta was expelled.

There was but a moderate amount of hemorrhage, as the uterus seemed to contract fairly well. The patient was now breathing easily, but was quite unconscious, making an effort to open the eyes, if spoken to in a raised tone of voice; the pulse was of fair strength and regular. I found that she could swallow, and ordered a few ounces of milk, which was slowly given. She remained in this condition for about three hours, when another convulsion occurred, which was perhaps, as to tonic contraction and length of time, not so severe as the last. Shortly after this attack I relieved the bladder of several ounces of urine, and found it to contain about the same quantity of albumin.

I should have made use of chloral before this time; but as I was some distance in the country, and found that I had none with me, I was not able to do so. I obtained some, however, about two hours later, at which time there were evidences that another convulsion was about to occur. I immediately injected, per rectum, fifty grains, properly guarded with mucilage, having found that a less amount does not usually produce the desired effect. The woman was quiet from this time as to any evidences of contracture for nearly six hours (breathing as in sleep); when with the first evidences of muscular movements the same amount was again injected. I found this to be necessary at about the same intervals, until four injections had been administered; when all evidences of recurrence ceased. This was about thirty-six hours from the second attack. The bladder was relieved during this period at intervals of six or seven hours, each time of a few ounces of urine, which was of about the same character as to appearance and amount of albumin as the first drawn.

The patient remained unconscious for nearly fifty hours, but was able to take some nourishment, which was given in the form of milk at regular intervals, or at such times as she could be induced to swallow. From this time she slowly began to recover; her convalescence extending over a period of sixteen or seventeen days, during which time she suffered from amblyopia to such a degree as not to be able to recognize the members of her family or any object brought within the usual focal distance. There was a good deal of muscular tenderness, and quite marked prostration. The after-treatment was tonic and alterative, under which she made fairly rapid progress to complete recovery.

There are a few questions of importance which the treatment of this case suggests:

1. What of the importance of venesection for the relief of the condition?

2. What cases would be most likely to be benefited by it?

3. What of the use of chloral as a therapeutic measure, as against chloroform by inhalation and morphine by subcutaneous administration?

I believe, as to the first, that its prompt action renders it an agent of the utmost importance; that it relieves the brain by lessening the force of the circulation and consequent arterial tension, and many times wards off a serious brain-lesion; but that it be practised early is of the utmost importance, before irreparable injury has been accomplished. Again, it gives us time to make use of other remedial agents, such as will relieve the general oppression, and, as a prominent writer has said, favors absorption and renders the patient more susceptible to their influence.

Secondly, I believe that women of full habit, with suffused face, and full, slow pulse, showing much arterial tension, will always be greatly benefited by venesection. My personal experience has been that when this important measure has been neglected the difficulty has much more frequently proved fatal. I call to mind in this connection, eight cases, seven of which were consecutive, that I treated by bleeding, three with the addition of chloral to the treatment, with a mortality of one—that one a primipara six months advanced. She was a person of full habit, had two very severe convulsions before I saw her, and, although I bled her freely, there was no return to consciousness; and I judged from the evidences that a serious brain-lesion had taken place early, perhaps with the first seizure. Barquissau says: "It diminishes the general mass of the blood; relieves the nerve-centers, which have a tendency to become congested; and by making the spinal bulb anemic, we deaden reflex irritability, which keeps up the hyperemia and by which the convulsive attack may be revived."

It is now somewhat more than twenty years since chloral hydrate became generally known as a remedy in the treatment of eclampsia, either by the mouth or otherwise. My first experience in the use of it was subcutaneously. I was called in consultation in a very severe case, in which the patient had suffered from a number of convulsive seizures after free venesection. I had seen, a few days before, an article in one of our journals with regard to the use of chloral hydrate subcutaneously in these cases. I advised it, and we made trial of it, injecting freely in the lower extremities. It relieved our patient, but it was some time before the ulcerations, resulting from the irritation caused by the chloral, were healed. I have since used it per rectum (thereby avoiding a repetition of my first unpleasant experience), as it is much more quickly and easily administered in this way, and as many times it cannot be given by the mouth. I should certainly much prefer it to chloroform; for, although chloroform arrests the convulsive seizures, it usually does so only for a short time, and the patient cannot be kept under its influence for a considerable length of time without danger. Some of the more prominent objections to its use that have been mentioned are that it produces congestion of the

nerve-centers, and so may increase cerebro-spinal congestion; also the asphyxia, to which complication there is a predisposition. Depaul admits that to a certain extent it does modify the eclamptic attacks, but says: "They exist none the less, as well as the complications—congestions, central hemorrhages, pulmonary congestions, etc."

There is no doubt but that we have in morphine and chloroform valuable remedies, the effects of which have been closely and practically investigated by the profession, and that they have held their place in professional confidence. Still, it seems to me that some of the arguments presented, especially those against the long-continued use of the latter, are well chosen. As to morphine subcutaneously, I could fully indorse its use, in doses not to exceed a quarter of a grain, to be repeated in case it be found necessary within a limited length of time, say one hour; but I should fear the heroic doses recommended by some writers, of from one-half to one grain, and boldly repeating upon evidences of recurrence; notwithstanding the fact that great tolerance of the drug has been urged in the eclamptic condition.

More definitely as to the last proposition, I believe that we have in chloral hydrate an agent of wonderful therapeutic value for the relief of reflex irritation; and that in the two, venesection first, judiciously, promptly, and boldly done, followed by chloral if the convulsions continue, we have measures that will never be supplanted by any more perfect or potent. After an experience of twenty-seven years of active practice, I can recall many cases treated in this manner, and the great majority have recovered: some by venesection alone, others by venesection and chloral hydrate combined. The former has, however, been my sheet-anchor, and I firmly believe that, if early and judiciously done, it will in the future, as it has in the past, save many mothers from an untimely death.

NEW DEVICE.

A SPLINT FOR FRACTURES AND LUXATIONS AT THE ELBOW-JOINT.[1]

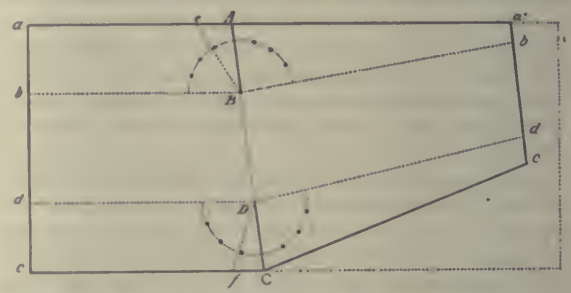
BY CHARLES W. DULLES, M.D.,
SURGEON TO THE RUSH HOSPITAL AND SURGEON TO OUT-PATIENTS AT THE PRESBYTERIAN HOSPITAL, PHILADELPHIA.

INQUIRIES in regard to a splint that I have devised for the treatment of fractures and luxations at the elbow having come to me, in consequence of a reference to it in a paper on "Fractures of the Arm," by Dr. John B. Roberts (*Annals of Surgery*, July, 1892), induce me to publish a description of it.

It is well known, and especially since the instructive publications of Dr. Oscar H. Allis on this subject, that one of the chief obstacles to the successful treatment of fracture at the elbow depends upon the difficulty of preserving the normal relation between the principal axes of the arm and forearm. The normal relation of these axes, when the arm is extended, is that of the two lines of an obtuse angle; and to preserve this, a certain number of surgeons have recently advocated and practised the treatment of fractures at the elbow by maintaining the forearm in full extension; for the reason that treatment by means of angular splints is often followed by displacement of one of the condyles of the humerus with loss of the normal abduction (outward, or radial, deviation from the plane of the axis of the humerus) of the forearm.

Ever since this danger impressed itself sufficiently upon my mind I have been using a splint which has proved quite satisfactory in my hands.

This splint, I make, for each case, from a sheet of light tin or sheet brass. On such a sheet I rule lines, guided by the sound arm, to mark out the relation of the axis of the forearm to that of the upper arm with the whole member extended. I then mark the points of the articular surfaces of the internal and external condyles and draw a straight line across the metal, passing (see figure) through them. With a strong pair of shears I then cut the whole splint out of the metal, and cut from the angles at the inner and outer sides toward the middle line (in the figure, from *A* to *B* and from *C* to *D*). I then make a few holes with an awl, as shown on the dotted semicircle, and bend the sides (*A a b B*, *C c d B*, *A a′ b′ B*, *C c′ d′ D*) backward (as the splint is to be reversed for



the injured arm) so as to form two troughs, and bend these troughs exactly along the line *B D*, so as to make an angular splint. Fixation at the angle required is secured by passing through the holes at the sides an ordinary brass paper-fastener and bending its ends over. The different holes permit of flexion at various angles greater than a right angle, and by cutting away from *E* to *B* and from *F* to *D*, different degrees of acute angulation may be obtained. Suitable padding with wool (which I prefer to cotton) completes the preparation of the splint, into which the arm is placed, with the forearm in supination, and in which it is confined by means of a bandage.

The splint is light and comfortable, and it permits examination of the joint at any time, without danger of displacement of the fragments, by simply removing the enclosing bandage. In describing it, I do not think it necessary to speak of the means for reducing or preventing traumatic swelling, which are guided by the principles so admirably taught by the late Mr. Sampson Gamgee.

The idea of the splint is to take a piece of light metal and convert it into a trough, the shape of which shall conform to the lines of the arm in extension; then to flex this trough along a line which corresponds with the true plane of the elbow-joint.

An examination of such a splint will show that it conforms to the proper lines of the arm and forearm in extension, and that on flexion the lower trough follows

[1] Read before the Philadelphia Academy of Surgery, December 5, 1892.

very closely the line of movement of the forearm as it approaches the humerus. At the same time it will be seen that the point at the angle in which the upper end of the ulna rests in flexion is lower than that in which the upper end of the radius rests, as should be the case, to conform the normal anatomic relation of these parts and the normal relation of the internal condyle of the humerus to the external condyle. The ulna being at the elbow-joint a thicker bone than the radius, it is well to have the wool cushion on the radial side a trifle thicker than on the ulnar side; but in many cases of fracture the first swelling compels one to adapt the cushioning rather to the condition of the soft parts than to the absolute size of the bones and the position of their surfaces.

A splint of this sort can only approximately imitate the conditions of the elbow-joint; but I think it does imitate them in a way conducive to good results in the treatment of fractures. So far as my experience goes, the results have justified my expectations.

Of course, I do not imagine that any one form of splint will prove suitable to every case; but this splint is light, clean, comfortable, and easy to apply, while permitting frequent examinations without risk to the position of the fragments, and changes of the degree of flexion as often as may be necessary, in each maintaining the normal relation of the axes of the arm and forearm.

A study of the elbow-joint, with a view to securing the proper position of the parts after fracture, has led me to believe that good results may be obtained by flexing the forearm quite fully upon the humerus, in which position both ulna and radius act as natural splints to the condyles. On writing this to Dr. H. L. Smith, of Boston, with whom I have had some correspondence on this subject, he tells me that he has already experimented on the cadaver in this direction, with the result of showing that, by this method (the forearm being semi-pronated), the condyles were fixed in a correct position. He has also treated some cases of accidental fracture in the same way, with good results.

If this experience should be repeated and confirmed by others, the splint for elbow-joint fracture would probably be a simple V-shaped one, placed against the outer side of the arm and the back of the forearm. With such a splint I am now treating an inter-condyloid fracture of the humerus. The patient is entirely comfortable; the bones appear to be in correct position, and I hope for a good result.

4101 Walnut Street.

MEDICAL PROGRESS.

Biologic Therapeutics.—In a recent address delivered at the New York Post-Graduate Medical School and Hospital, Dr. Wm. A. Hammond stated that he had prepared and had employed therapeutically extracts from the brain, spinal cord, testicles, ovaries, pancreas, stomach, and heart, which he calls respectively, cerebrin, medullin, testin, ovarin, pancreatin, gastrin, and cardin. The process of preparation of the brain, from which that of the other organs does not differ, consists, after its removal, in washing the organ in water acidulated with boric acid, and cutting it into small pieces with a mincing machine; then to 1 part of this, in a wide-mouthed glass-stoppered bottle, are added 3 parts of a mixture of equal parts each of a saturated solution of boric acid in distilled water, pure glycerin, and absolute alcohol. After standing in a cool place for at least six months, being well stirred or shaken two or three times a day, the mixture is permitted to pass through a porous stone filter. The residue upon the filter is enclosed in several layers of aseptic gauze and subjected to a pressure of over a thousand pounds, the exudate being permitted to fall upon the filter, and being mixed with a sufficient quantity of the filtrate to cover it. When it has entirely filtered through, it is thoroughly mixed with the first filtrate, and the process is complete. The greatest precautions are taken to prevent contamination. Turbidity can be overcome by filtration. Five minims of this extract, diluted, constitutes he dose for subcutaneus injection. The most notable effects of the injection are an increase in the frequency, strength, and fulness of the pulse; a feeling of distention of the head; increased perspiration; flushing of the face; occasionally headache; a sense of exhilaration; increased elimination of urine; increase of muscular strength and endurance; improvement of vision; increased appetite and digestive power. Two injections should be given daily, or on alternate days. Dr. Hammond reports that he has successfully employed cerebrin in various affections of the brain and spinal cord, including congestion, neurasthenia, migraine, hysteria, melancholia, hebephrenia, paralysis, neuralgia, sciatica, epilepsy, general paresis. In some cases cardin and testin have also been used. In explanation of the rationale of the method of treatment, it is suggested that in health every organ separates from the blood the special pabulum that is essential for its perfect nutrition and function, while in disease this selective action is perverted or lost. By supplying artificially, in cases of disease, the special product of the organ at fault, it is hoped to reëstablish the equilibrium.

Diaphragmatic Hernia.—Annequin (*Archiv de Méd. et de Pharm. milit.*, xxi, 1, p. 33) has reported the case of a healthy soldier, who for two years had suffered from recurrent attacks of severe collicky pain, referred especially to the epigastrium, unattended with diarrhea, and usually induced by active muscular exercise, and who, following some excessive physical effort, was seized with pain of unusual severity and with syncope. The pain failed to yield to the local employment of poultices and to anodyne enemata, but continued with paroxysmal exacerbations. In the course of a little while symptoms of intestinal obstruction appeared. The face became drawn, the nostrils distended; the respiration shallow and sighing; the pulse small, compressible and frequent; the extremities cold; the temperature subnormal; the urine deficient in amount, without other abnormality; the breath offensive. There was, however, no hiccough; the abdomen was retracted, except in the epigastrium; there was no evidence of the presence of an abdominal tumor or of hernia in any of the situations in which such a condition is wont to occur. There was no tenesmus, and anus and rectum presented no lesion. The abdominal pain was intense, but intermittent, and localized deeply in the epigastrium. Neither flatus nor fecal matter had been passed by the bowel for three

days. Liquids ingested were rejected at once. From time to time there was vomiting of a bilious fluid that had a fetid odor. The heart presented no abnormality. The respiratory movement was thoracic and restricted; the vesicular murmur was enfeebled. As the nature and situation of the obstruction could not be determined, and as the condition of the patient was considered too grave for operative interference, symptomatic treatment was instituted. Four days and a half after the onset of the attack, and thirty-six hours after entering the hospital, the patient succumbed. At the post-mortem examination a knuckle of the large intestine, at the junction of the transverse and descending colon, together with a portion of omentum, was found to have made its way through an opening in the left leaflet of the diaphragm. The bowel was situated behind the gastro-splenic omentum and in front of the kidney, and lay between the heart and the adjacent lung. The omentum had formed adhesions to the upper surface of the diaphragm and to the pericardium. Reduction could not be accomplishsd by simple traction. The stomach occupied a vertical position, and was twisted upon its axis. The duodenum was flattened and twisted, so as to be practically impassable.

Poisoning by Sardines.—STEVENSON (*British Medical Journal*, No. 1668, p. 1326) has reported the case of a military officer, twenty-one years old, apparently in good health, who, after making a breakfast of six hot sardines, some toast and coffee, became ill, vomited several times, and on the following day died. At the post-mortem examination the whole body, as well as the mucous membrane of the stomach and bowels, was found emphysematous. Some of the sardines obtained from the box that had contained those that the dead man had taken proved fatal to white mice to which they were fed. An alkaloidal substance obtained from the fish also proved lethal to mice. No characteristic bacteria were found in the sardines, in the gastric or intestinal contents, or in the liver. Animals treated with fragments of the liver and of the stomach succumbed. An alkaloidal substance possessed of toxic properties was obtained from the vomited matter and from the gastric contents.

Measles with Relapse.—STRENG (*Deutsche medicin. Wochenschr.*, 1892, No. 48, p. 1084) has reported the case of a six-year old girl, who for three days had had chilly sensations and impaired appetite, and for twenty-four hours a cutaneous eruption. The temperature was 99.8°, and rose no higher. The eruption was typical of measles. Conjunctivitis, rhinitis, and bronchitis were likewise present. On the seventh day after the appearance of the eruption, a purulent discharge from the right ear made its appearance, the temperature mounting to 101°, but declining almost to the normal in the course of the next two days. The eruption disappeared; the catarrhal symptoms subsided; and the subjective condition was good; when, on the tenth day, the temperature began to gradually rise, on the twelfth day reaching 103.8°, the morbillous eruption reappearing simultaneously; to these manifestations, conjunctivitis, rhinitis, and bronchitis were soon added. On the night of the fourteenth day the temperature declined by crisis, and thereafter convalescence was progressive, though further complicated by an eruption of pemphigus vesicles on the right ear and on the fingers of the right hand.

Actinomycosis of the Lip.—MARI (*Centralbl. f. Bakteriologie u. Parasitenk.*, xii, 24, p. 854) reports that in 1889, Klepzow, veterinary surgeon to the abattoir of Moscow, found beneath the mucous membrane of the lower lip of some slaughtered oxen hard, movable nodules of the size of peas or of small nuts, in the purulent contents of which were actinomyces. The observation was confirmed by other investigators, and among 2000 animals 112 cases of actinomycosis of the lip were discovered. In the months of March, April, May, and June, 1892, among 42,230 head of cattle slaughtered, 1030 presented actinomycosis, which in 621 was seated upon the lip. Section of a nodule disclosed a grayish-yellow point, often softened and purulent at the center, and in the pus the characteristic ray-fungus could invariably be demonstrated.

THERAPEUTIC NOTES.

Chloralose is the name given by HANRIOT and RICHET (*La Semaine Médicale*, 1893, No. 2, p. 14) to a crystalline body resulting from the action of anhydrous chloral upon glucose. The substance is exceedingly bitter, readily soluble in hot water, less readily in cold water. Adults will tolerate from seven and one half to fifteen grains, although from three to six grains are sufficient to produce calm, dreamless, refreshing sleep. The drug was borne by persons that could not take chloral or morphine, or in which these drugs failed to produce sleep.

Pancreatic Juice for Diabetes.—MACKENZIE (*British Medical Journal*, No. 1672, p. 63) has reported the employment of liquor pancreaticus, in half-ounce doses, given three times a day, immediately after food, in the treatment of two cases of diabetes mellitus, with benefit. Languor and lassitude diminished; the thirst lessened; and the quantity of urine became smaller, although the specific gravity of the urine and the percentage of sugar remained unchanged. In a third case similar results were obtained.

For Chancroid.—

℞.—Acid. carbolic. . . . . ʒij.
Camphor. . . . . ʒv.—M.

S.—Apply topically by means of absorbent cotton, twice daily.

Sodium Borate in the Treatment of Paralysis Agitans.—SACAZE (*La Semaine Médicale*, 1893, No. 4, p. 14) reports the case of a man, thirty-eight years old, in which the administration of sodium borate in doses of from 15 to 45 grains, in three or four equal parts in the course of the day, was followed by the most striking improvement in the symptoms of paralysis agitans that had developed after a fall upon the shoulder.

METHYLENE BICHLORID.

IN his recent admirable work on anesthetics, DASTRE[1] observes that there is a true and false methylene chlorid, and that the true chlorid is not an anesthetic. If we inquire into the grounds of this opinion, we shall be puzzled to account for so dogmatic a statement. We find on examination that there are four different substances laying claim to the same appellation. For the sake of clearness they may be thus enumerated: First, there is the mythelene bichlorid prepared by ROBBINS, and described as "the distillation of chloroform and alcohol on zinc." It seems to be the true anesthetic, and has been used with success by SPENCER WELLS and RICHARDSON in England, and in France by MM. LE FORT and LABORDE.[2] Secondly, there is a mysterious substance, of English manufacture, which PROF. REGNAULT found on analysis to be a mixture of chloroform and methylic alcohol.[3] Believing this mixture to be the true anesthetic, he prepared a pure specimen, of which the proportions were 4 volumes of chloroform and 1 volume of methylic alcohol. His two colleagues, POLAILLON[1] and LE FORT tested it in their practice, and judged it dangerous. It is, in fact, not sufficiently powerful to produce insensibility in men. For women it answers tolerably. In physical properties it differs markedly from the English preparation of ROBBINS, which, as we have said, seems to be the real anesthetic, though not the real methylene chlorid. The real chlorid, of which the formula is $C_2H_2Cl_2$, was isolated by REGNAULT and VILLEJEAN,[2] and two careful physiologic studies revealed its utter uselessness as an anesthetic. We cite, for the light they throw on certain cases of death from the commercial drug, a few sentences from the last excellent paper of REGNAULT and VILLEJEAN: "At the present time we can assert, basing our opinion on the results of more numerous and more precise observations, that if chloroform brings on, at the same time as the general anesthesia, a state of muscular relaxation most useful in surgical operations, methylene chlorid on the contrary produces, during the inhalation and also after the inhalation, a state of (muscular) contraction both temporary and permanent, alternating with cries of a choreic and epileptiform character."

Such, indeed, are the symptoms noted in some cases of poisoning. Is it, then, to be thought that poisoning is sometimes or often caused by the real methylene chlorid? Such an assumption, we confess, is somewhat hazardous, for we have not been able to discover that the true chlorid is ever made in its purity except in the savant's laboratory. We lay stress upon this matter, first, because the question serves to make clear an element of uncertainty and danger in the use of the commercial drugs which profess to be methylene chlorids, when they are nothing but mixtures, of shifting and doubtful constitution. And lastly, some of these mixtures are definitely known to possess dangerous impurities, as DR. HENRY E. ARMSTRONG[3] has shown.

Having thus distinguished the four different substances (now) called by courtesy methylene bichlorid, of which we have any particular experience, let us come to the essential part of the whole question.

If we look now into the history and nature of ROBBINS's drug, we shall meet with one of the most singular facts in the study of this rather obscure

subject. Although this drug is an undoubted mixture,[1] yet it differs in appearance and effect from a chemically pure mixture of chloroform and methylic alcohol prepared by REGNAULT, and well known in France as the *liqueur de Regnault.* On this interesting subject LE FORT says: "Whatever may be the results of chemical analysis, I affirm that the mixture of M. REGNAULT is not identical with the liquid I procured from London; the physiologic results are too different."[2] In another place he gives an account of his unsatisfactory experience with REGNAULT'S mixture. On the other hand, in speaking of the English drug, which he had used repeatedly during a period of six years, he is scarcely less reserved in his praises than SPENCER WELLS.

Here is a *résumé* of LE FORT'S last experiences: methylene bichlorid was employed 33 times, of which 16 cases were in men and 17 in women.

Results in men:	
Mean quantity used	15 grams.
" duration of the initial stage	13 minutes.
" " " anesthesia	32 "
Agitation, light	9 cases.
" severe	1 case.
Vomiting during the operation	1 "
" after " "	3 cases.
Results in women:	
Mean quantity used	10 grams.
Initial stage	8 minutes.
Duration of the anesthesia	32 "
Agitation, light	2 cases.
" severe	1 case.
Vomiting during the operation	1 "
" after " "	3 cases.
Fifty-eight cases with *chloroform* gave the following results:	
Mean duration of the initial stage	7 minutes.
" " " anesthesia	22 "
Agitation, light	23 cases.
" severe	7 "
Nausea and vomiting during the operation	6 "
" " " after " "	22 "

Whether these results show absolutely that methylene bichlorid is superior to chloroform as an anesthetic, it is not necessary to say. No one, as far as we know, has ever denied that it is safer than chloroform; and, as safety is in the long run the only point in these matters well worth discussion, we shall examine a little further the evidence for the English drug. SIR SPENCER WELLS, by far its most important witness and most plausible panegyrist, says: "I have now done ovariotomy 1138 times, and with the exception of about ten,[1] where for some reason or other chloroform was used, chloromethyl was the anesthetic employed." Again: "Its chemical composition shows it to differ from chloroform only in containing one equivalent less of chlorine,[2] and in a letter to LE FORT, SPENCER WELLS doubts whether the preparation of ROBBINS is, chemically speaking, true methylene bichlorid; but practically it is the best and surest anesthetic he has ever used.[3] It must be given freely diluted with air, a task accomplished best by means of JUNKER'S inhaler. In this way but from 2 to 4 per cent. of vapor is administered. To neglect of this rule he attributes a fatal accident at the Plymouth Hospital."[4]

These quotations show that SPENCER WELLS'S success, setting aside his personal ability and skill, has depended first upon some inherent excellence in ROBBINS'S drug, an excellence due perhaps to its containing less chlorine than chloroform, and to its nature as a mixture; and, secondly, upon the rigid observance of sound technique in the administration. Upon taking care, as we have ourselves noted personally and in our reading, depends all success in the use of anesthetics; and many malapert operators, by ignoring some sound method of manipulation, have hindered the development of practical skill—especially, it is to be added, in the administration of chloroform. In the present instance the care we wish to insist upon is, as experience shows, to be exercised in the choice of the means of inhalation. It is a matter of vital importance to afford a regular and graduated amount of vapor to the patient.

There have been not a few deaths from methylene bichlorid. In the *Lancet*, during the last ten years, there are accounts of seven, and this number, it is safe to say, represents but a fraction of the truth. DASTRE, we think, has summed up very shrewdly the defects of this agent, and we are disposed to concur with him in his disparagement of it. According to him, it possesses the defects, and not all the virtues, of chloroform, and deaths from it are much more frequent than its advocates admit. Certainly it is hard to have confidence in a mixture in many ways dubious—a mixture that seems to differ, though for the better, from one of the

same proportions made by a highly accomplished chemist. Yet it must be said in favor of Robbins's mixture, and others like it, that the worst it has apparently done is to cause vomiting and unrest. We say "apparently," for the reported circumstances of fatal cases, with the single exception of the choice of an inhaler, are too obscure to be handled.

TUBERCULOUS INSPIRATION-BRONCHO-PNEUMONIA.

One of the most alarming manifestations in the clinical history of a case of pulmonary tuberculosis is hemoptysis, which may be of varying degree, from a slight admixture of blood with the sputum to a pint or more. The complication is of itself rarely fatal; occasionally, however, it causes death by asphyxia, the patient literally being drowned in his own life's blood.

At one time in the past a belief was current that in some instances pulmonary tuberculosis developed in the sequence of hemorrhage from the lungs. It required the elucidation of the etiology of tuberculous processes in general to finally demonstrate the fallacy of this view. Now, it is universally admitted that in such cases the pulmonary lesion was primary, not attracting attention until the occurrence of the hemorrhage.

Bäumler (*Deutsche medicin. Wochenschr.*, 1893, No. 1, p. 1) calls attention to a form of broncho-pneumonia that may occur in cases of pulmonary tuberculosis from the inspiration of blood and the contents of pulmonary cavities (including pyogenic cocci and tubercle-bacilli), in conjunction with hemoptysis. A similar condition may arise in the absence of hemorrhage, or in connection with an ordinary bronchiectatic cavity, but under these circumstances the course of the case is generally much less unfavorable.

The tuberculous inspiration-broncho-pneumonia may occur in cases in which a pulmonary lesion is not even suspected, or in which a tuberculous lesion has undergone retrogressive change. It is usually preceded by some form of active physical effort, and commonly pursues a rapid course, presenting the characters of an acute infectious disease, and leading to a fatal termination. The first manifestation is usually hemoptysis, which may persist in moderate degree for a number of days. The febrile movement is decided, and the temperature usually reaches a considerable height. Dyspnea is marked, and cyanosis becomes pronounced. On physical examination the signs of a diffuse broncho-pneumonia will be found. Careful examination of the sputum will detect tubercle-bacilli. After death a tuberculous cavity, containing a ruptured blood-vessel, will be found in one or in both lungs, and, besides, a lobular pneumonia; miliary tubercles may also be present, but not as a rule in any considerable number.

The clinical picture differs from that of enteric fever in the abruptness of onset, in the rapidity of course, in the period at which the pulmonary symptoms appear, and in the occurrence of hemoptysis. A knowledge of the previous history is important. Tuberculous inspiration-broncho-pneumonia sets in more abruptly than acute miliary tuberculosis; pursues a more rapid course; is attended with a higher febrile movement; cyanosis appears earlier; and the physical signs are distinctive. From ordinary broncho-pneumonia the tuberculous variety differs in the occurrence of hemoptysis and in the presence of tubercle-bacilli in the sputum.

The prognosis is always dubious, and as a rule unfavorable.

The treatment is purely prophylactic. Patients with pulmonary cavities, and with tubercle-bacilli in the sputum, should be cautioned against indulging in too active physical exercise; and as the existence of cavitation is not always demonstrable, great circumspection should be used in advising pulmonary gymnastics. These patients should avoid irritating atmospheres. When a tendency to hemoptysis manifests itself, they should be enjoined to observe the most perfect rest.

EDITORIAL COMMENTS.

Mixed Tuberculous and Typhoid Infection.—It is a well-known clinical fact that the differentiation of typhoid fever and tuberculosis (particularly of the acute variety) is sometimes exceedingly difficult; and that in a given case, in which the symptoms and physical signs of tuberculous disease become perfectly clear after an attack of what was supposed to have been typhoid fever, it may be impossible to say positively whether the febrile affection acted merely as a predisposing factor in the development of the secondary condition or the original primary disease was really tuberculous.

As an illustration of the difficulties of diagnosis, a case recently reported by Senator (*Charité Annalen*, 1892, xvii, p. 372; *Schmidt's Jahrb.*, 1892, No. 1, p. 29) is most interesting. A man, twenty-one years old, without hereditary predisposition, for a week presented

pulmonary symptoms and moderate fever; and for the next four weeks a continuous febrile movement, together with pain in the right iliac region and gurgling, rose-spots, enlargement of the spleen, liquid stools, and diazo-reaction of the urine. Examinations failed to disclose the presence of either tubercle-bacilli or typhoid-bacilli. The diagnosis lay between enteric fever and miliary tuberculous, and finally both were suspected. Death took place after an illness of five weeks. At the post-mortem examination the lesions of pulmonary and intestinal tuberculosis were found.

Cases are not wanting in which typhoid fever has occurred in a tuberculous patient, but the records are scanty (if any at all exist) of cases in which the simultaneous existence of the dual infection has been demonstrated. Without giving the clinical history, Kiener and Viellard (*Compt.-rend. hebdom. des Séances de Soc. Biologie*, 9. sér., tome v, No. 1, p. 14) report such a case that terminated fatally. At the post-mortem examination the lesions of an acute, disseminated, granular tuberculosis were found in lung, pleura, peritoneum, and pia mater. The lower third of the ileum presented the typical ulceration of third week of typhoid fever, while higher up in the bowel were the granulations of the tuberculous process. Bacteriologic examination of material obtained by puncture of the spleen disclosed the presence of bacilli that correspond in all particulars with typhoid-bacilli.

No Code.—The New York State Medical Society has adopted the following resolutions:

"*Resolved*, That the Society reserves to itself the right to punish its members for any unprofessional conduct.

"The determination of what shall be considered unprofessional conduct shall rest with the Society. If at any time charges are preferred against a member of the Society, these charges are referred to a committee which already exists for a similar purpose. This rule shall take the place of paragraph eight of chapter six of the by-laws, as well as the rules adopted by this Society in February, 1882.

"*Resolved*, That the Society deems it unwise, at this time, to appoint any committee of conference with the American Medical Association upon the subject of medical ethics, as requested by that distinguished body; but the Society ventures to express the hope that the American Medical Association, at no distant day, will take such action as will remove the merely technical obstacle to the most cordial coöperation between the two societies."

Whether or not this action be politic and judicious and ethical remains to be tested by the logic of events. It is a sort of *j'y suis, j'y reste* argument, about which the logic of controversy is of little use. There has certainly been too much controversy already. Let us quit arguing and try to unite in harmony. It is certainly a fact of profound significance for the American medical profession, and one that it behooves us all to consider most carefully and seriously.

The Physician and the Sectarian.—In a most intelligent paper recently read before the Homeopathic Medical Society of the State of Pennsylvania, Dr. Clarence Bartlett (*Hahnemannian Monthly; The Clinical Reporter*, vi, i, p. 20) recommends, in the treatment of the conditions that predispose to the occurrence of apoplexy, glonoin (nitro-glycerin), arsenic, arsenic iod., phosphorus, belladonna, and nux vomica. These, together with "abstinence from meat-diet and alcoholic beverages, moderate indulgence in eating, a quiet life, the free drinking of water, the avoidance of exciting emotions," are considered "simply indispensable." "When collapse is not present, the application of ice to the head has a beneficial effect, as it serves to excite contraction of the cerebral vessels. When collapse is present, mustard plasters to the nape of the neck have been recommended by Gowers as of value in inducing reflex contraction of the arteries." In the apoplectic attack, aconite, glonoin, opium, and other remedies are recommended to meet various indications. Now, had the article from which we quote appeared in any other than a self-styled homeopathic journal, it would scarcely have been possible to have discerned that the writer was a so-called homeopath. The various measures recommended are those that are practically employed by all honest physicians. The question of homeopathy, the question of dogma, does not arise. The fact is that the true physician will use any remedy, whatever its source, whatever its mode of action, that will alleviate suffering or cure the disease; it matters not whether the use be designated allopathic, homeopathic, eclectic, or what not. It is a cause for sincere regret that any body of men will permit their sphere of usefulness to be restricted by blind adherence to a dogma or will be parties to at least tacit deception by its pretended acceptance.

Carbolic Acid as an Antiseptic.—The swing of the pendulum is bringing antiseptic surgeons back to the point from which they set out. With the knowledge that wound-complications were almost invariably dependent upon contamination by living matter, efforts were directed to the finding of a body capable of preventing such contamination, without at the same time causing injury. Of all the antiseptics proposed or used, carbolic acid and mercuric chlorid are the two that have shown themselves most deserving of confidence, and the second has been much more largely used than the first. Recent developments have, however, tended to demonstrate that mercuric chlorid is not the perfect antiseptic that is has measurably enjoyed the distinction of being; and now comes the interesting announcement that Sir Joseph Lister (*British Medical Journal*, No. 1674, p. 163) has practically repudiated mercurial solutions for antiseptic purposes in surgical procedures, and has returned to the use of carbolic acid, which, in the strength (1:20) in which it is ordinarily employed, he shows to be germicidal to most of the noxious organisms.

A Lay View of Dispensary-abuses.—The general public, according to the New York newspapers, is awakening to the fact that the medical treatment of 300,000 or more people in one city by charity in the year 1890 is a fact worth considering. One writer takes the curbstone view of the question, and with surprisingly poor but popular logic, he argues that if the doctors are willing to pauperize themselves and degrade their profession, what is that to the public? Let the public most cunningly take all it can get without pay and without thanks. Whether to get clinical material or to beat rivals in the statistical showings, or from whatsoever motive, matters not. The indiscriminately free dispensary, it is moreover averred, is also justified by the fact that the out-and-out quack

is thus headed off. This is regardless of the fact that the quack were better beaten by public laws that the public will not allow to be passed, and also that the more preposterous the dispensary-abuse, the more outrageous the quackery rampancy.

Popularization of Medical and Hygienic Knowledge. — When one considers that quackery and impostures of all kinds, together with the diseases on which they thrive, are most luxuriantly manured by popular ignorance of physiology, hygiene, and medicine, the true physician must sympathize with every sincere attempt to enlighten the people in regard to these matters. In this connection we wish to direct attention to the work being done by Dr. Remondino in *The National Popular Review*, the specific scope of which is the field of preventive medicine and popular hygiene. Every month this tasteful and tactful periodical contains excellent articles designed to clarify the minds of its readers as regards sanitation, sound principles of dress, personal and communal hygiene, and especially with enlightened views as to the true aim and practice of the physician. As a plebificator of scientific medicine it is unrivaled.

Dr. Billings's Estimate of the Medical Profession as a Calling.—Every physician who loves his profession will be delighted to read the manly and sympathetic plea for it made by Dr. Billings in the last number of *The Forum*. Medicine does not bring the fame and money that may be gained in other callings, but it unites the intellectual, the moral, and the practical exercises of the mind in a happy and satisfying manner equalled by none other. Other motives than those of the love of humanity, of science, and of self-respect are often enough those of the medical student and practising physician—it does not need Philistinic criticism to tell us that—but in other professions the other motives and the Philistine himself are more at home than in ours.

The Sneak Advertiser, according to the resolution of the San Francisco County Medical Society, is not a person wholly above suspicion. He is to be expelled, if his name "appear in the daily press describing his professional powers in an unprofessional manner and he cannot give a satisfactory explanation" of the fact. That the wicked reporter or injudicious assistant was not allowed to be put into service as a scapegoat is shown by the Society's action in expelling four such offending members. There is evidently an end and even a reversal of the (untrue) dictum that "Manners and morals grow uniformly worse as one proceeds Westward."

Publication of Papers Read at the Pan-American Medical Congress.—Physicians are often prevented from giving their best literary work to societies, associations, and congresses because of the rule that papers contributed may not be published elsewhere than in the Transactions or special Journal of the society. This rule often works to the injury of the society and of the contributor. We are glad to learn that papers read at the Pan-American Congress may, after the meeting, be published in full in whatever journal the author pleases.

The Excelsior College of Medicine, a bogus institution, driven out of Massachusetts, has come to grief in New York, where its proprietor, a "Doctor" Booth, sold a *Herald* reporter a diploma for $50, and was the next day put in jail. If the *Herald* could secure them, and would devote an equal amount of space to publishing the examination-papers of some of the "legitimate" M.D.'s of some of the "reputable" medical colleges, it would do a still greater service to the community, and to medicine.

SOCIETY PROCEEDINGS.

THE NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, held at the New York Academy of Medicine, February 7, 1893.

DR. ALFERD WIENER presented a "Subacute Case of Unilateral Bulbar Palsy." The patient was a young man of seventeen years. The family history was negative. Nearly two years previously the glands on both sides of the neck, in the region of the sterno-cleido-mastoid muscles, began to enlarge. More than a year later one of these glands on the right side suppurated, and the pus was evacuated. Soon after this, the remaining glands began to give rise to so much discomfort that those on the right side were removed, together with a large portion of the sterno-cleido-mastoid muscle. A little later the glands on the left side were removed. Examined microscopically, the glands proved to be tuberculous. After two months more it was noticed that the patient's tongue, on protrusion, deviated to the right side; this was followed by hoarseness and difficulty in swallowing, and later on by distinct atrophy of the middle half of the tongue. On electric and laryngoscopic examination it was found that there was complete right-sided palsy, involving the tongue, soft palate, pharynx and larynx, together with paralysis of the sterno-cleido-mastoid and upper portion of the trapezius muscles. The lesion in this case, it was pointed out, might be situated at a point just external to the exit from the skull of the pneumogastric and spinal accessory nerves, namely, just behind the angle of the jaw; or on the surface of the medulla; or it might be nuclear. All the facts in this case lend support to the view that the lesion is a tuberculous one, involving the nuclei of the nerves that govern the palsied parts. These groups of cells form the conjoined nuclei of the spinal accessory, vagus, and hypoglossal nerves, and a very localized lesion in this part of the medulla would be sufficient to affect them. The involvement of the trapezius and sterno-mastoid muscles is probably due to injury to the nerve supplying them, while the laryngeal symptoms may be accounted for by a paralysis of the stylo-hyoid muscle (due to pressure from an enlarged gland) or by the unantagonized action of the muscles on the left side of the throat.

DR. GEORGE W. JACOBY presented a case of "Complete Atrophy of the Tongue with other Nuclear Symptoms." The patient was a female, thirty years old, whose mother had died of pulmonary tuberculosis. Her husband's sister had more recently died of the same affection, and had been nursed by the patient. For two months there had been gradual impairment of vision, which was found to be due to a slight atrophy of both optic nerves, and under internal treatment disappeared. The patient had also suffered from violent headaches, which disappeared

with the loss of sight. For three weeks there had been difficulty in swallowing and speaking. Vomiting occurred every morning on rising. At the first examination the tongue deviated to the left and there was marked atrophy of its right half. The uvula was deflected to the left, and there was paralysis of the left side of the soft palate. The patient had enlarged cervical glands. At a later date the atrophy of the tongue and soft palate became complete. Paralysis of the internal and external ocular muscles of the left side also developed. The case was thought to be one of progressive nuclear paralysis.

DR. B. SACHS stated that in Dr. Wiener's case a chronic nuclear condition must be excluded on account of the rapid progress of the symptoms, and because they had remained strictly unilateral. In Dr. Jacoby's case an element of doubt enters into the diagnosis, because of the rapid progress of the symptoms. They seemed to indicate the presence of some active lesion, specific or tuberculous.

DR. THEO. H. KELLOGG read a paper on "Modifications of Respiration in the Insane." To facilitate the study of these modifications, he grouped them as follows: A. Modifications of respiration as regards frequency, depth, rhythm, and sound. B. (1) Spasmodic expiratory modifications, such as occur in laughter, crying, sneezing, coughing, and snoring. (2) Spasmodic inspiratory modifications, as in singultus, chasmus, and laryngeal crises. C. Dyspneic modifications.

DR. C. A. HERTER made a report of a case of "Sarcoma of the Cervical Spinal Cord. Autopsy." The patient was a merchant, twenty-nine years old, who had noticed a loss of sensation, beginning as numbness, on the ulnar side of the little finger of the right hand. Soon the entire little finger was involved, and later the ring finger and the ulnar side of the middle finger. At the same time the anesthesia extended upward along the hand. In the course of three months the anesthesia had passed up the ulnar side of the forearm and arm, and had reached outward over the hand as far as the thumb. Pain also appeared on the ulnar side of the right forearm and hand; slight and occasional at first, later severe and of increased duration. This was followed by loss of power, first in the flexors of the fingers, then in those of the forearm. About five months after the first symptoms were noted, there developed atrophy of the first dorsal interosseous muscle. The wasting soon involved the muscles of the thumb and hypothenar eminence, and the flexors of the forearm. In about the eighth month the pain abated greatly. During the period of severest pain, the entire right arm became edematous. On electric examination made thirteen months after the appearance of the first symptoms, loss of faradic irritability in the right arm, and in all the extensors and flexors of the wrist and interossei, was found. Tactile sensation and the pain-sense were entirely lost along the ulnar border of the arm to the axilla, and were greatly impaired along the radial border as high as the shoulder. The temperature-sense (which was only roughly tested) appeared to be quite lost in the arm. There was almost an entire loss of the muscle-sense; the patient had no sense whatever of the position of the fingers, hand, and arm. The surface of the right arm was pale and much colder than that of the left. In the left hand and arm, power and sensation were apparently normal. Both legs were a little weak. Equilibrium was maintained without difficulty. The knee-jerks were exaggerated, in the greater degree on the right side. The power of the sphincters was unimpaired. There was no vertebral deformity, and no tenderness on pressure over any of the cervical or upper dorsal spines. Sight was unimpaired. The pupils reacted normally to light, and in accommodation. The right palpebral fissure was distinctly smaller than the left, and the right lid drooped a little. On examination of the chest there was found dulness on percussion over the upper part of the right side. The temperature was 101°; pulse, 100; respiration about 30 per minute. In the course of two weeks after this examination, the right leg became much weaker than it had been, and pain and numbness extended gradually down the entire left arm. Loss of power was also detected in the left leg. There was temporary retention of urine. In the course of a month a tense swelling was observed over the outer extremity of the right clavicle, and extending down into the axilla over the front of the shoulder. In the course of two weeks this tumor grew to the size of a child's head, became very tense, and was covered with greatly distended veins. The patient grew rapidly worse. Incontinence of urine and feces set in, and the breathing became labored, owing to paralysis of the thoracic muscles. There was total loss of sensibility extending as high as the crest of the ilium upon both sides, with bilateral impairment of sensibility as high as the third rib. Large bedsores appeared, and, sixteen months after the first symptoms, the patient died from exhaustion and respiratory failure.

A partial autopsy was made, and a mass removed from the clavicle, and another from the upper and posterior part of the thoracic wall. A number of tumors occupied the posterior and inner aspects of the right upper chest, displacing the lung. Some of these masses appeared to grow from the clavicle, others from the vertebræ, but their relations could not be distinctly made out. The specimen obtained from the spinal cord was five inches long, and extended from the eighth cervical to the seventh dorsal segment, both inclusive. Sections were made from the eighth cervical, and first, second, and third dorsal segments. The tumor involved at this level nearly the entire right half of the cord, and encroached anteriorly upon the left anterior column of the cord. Posteriorly, it did not pass quite to the posterior horn. The ganglion-cells in the region of the tumor had undergone partial or entire destruction, or were in some instances apparently replaced by small groups of spindle-shaped connective-tissue cells. In structure, the tumor was an exceedingly vascular spindle-celled sarcoma. Sections made from the mass, from the clavicle and thoracic wall, showed it to be a fibro-sarcoma.

While the anatomic diagnosis presented no difficulties, the pathologic diagnosis was made with some hesitation. The existence of signs of pulmonary consolidation, muco-purulent expectoration, hectic temperature, rather rapid emaciation and night-sweats, all suggested a tuberculous process, and the diagnosis of a secondary tuberculous tumor of the cord was thought to be justified. The alternative diagnosis was sarcoma, but the accuracy of this appeared improbable. An examina-

tion of the sputum was not made. Dr. Herter had collected twenty-six cases of sarcoma of the spinal cord, which he had compared with cases of massive tubercle of the cord. This study had shown that (1) Sarcoma of the spinal cord occurs with about equal frequency in the two sexes. (2) Sarcoma of the spinal cord is essentially a disease of adult life; massive tubercle, on the contrary, is a disease of adolescent and early adult life. (3) Etiologic factors in the development of sarcoma of the spinal cord are practically unknown. (4) In three cases of sarcoma, the first symptoms appeared during pregnancy. (5) Pain appears to be the earliest and most prominent symptom in four-fifths of the cases of sarcoma of the cord. (6) In sarcoma, the course of the disease is, in general, much slower than in tubercle.

THE PRESIDENT said that while sarcoma in general is more commonly met with in persons under the age of thirty, sarcoma in the nervous system is decidedly more frequent in adult life. He has recently collected 600 cases of tumor of the brain (300 in adults and 300 in children), and among these there were 34 cases of sarcoma in children, and 157 in adults. He was much interested in the collection of cases made by Dr. Herter, and thought it would be well to carry the investigations further and determine how many of these cases would have been suitable for operative interference.

DR. GRAEME M. HAMMOND expressed the opinion that the symptoms referred to the side of the body opposite to that invaded by the growth, might have been due to degenerative changes in the opposite side of the cord, caused by a cutting off of the blood-supply, or the commissural fibers may have been interfered with sufficiently to produce the symptoms.

DR. HERTER added that the case was seen by him at too late a day to be operated on.

DR. GEORGE W. JACOBY read a paper on "The Motor Disturbances of the Heart of Nervous Origin." He stated that in a large number (probably in more than one-half) of the persons who seek advice on account of some motor disorder of the heart, no anatomic lesion is clinically discoverable, and no mechanical cause can be found. In such cases it is reasonable to seek for the cause of the altered function in some disorder of the complicated nervous apparatus of the heart. The action of the heart may be intermittent, irregular, abnormally slow (bradycardia), or abnormally frequent (tachycardia).

Intermittency may be true or false; in the latter form the pulse fails, but the heart is regular, while in the former the heart actually drops a beat. In irregularity of the heart's action the number of pulsations varies from minute to minute, or the pulsations vary in height and tension. These forms of arhythmia may be persistent or only temporary: when persistent, they are probably due to some organic disease of the heart; when they are temporary, they are either dependent upon defective constitution of the blood, or are purely neurotic. Toxic influences associated with sexual excesses, and with the excessive use of tea, coffee, tobacco, and alcohol, are potent factors in the production of arhythmia. Intermittency may be due to even the moderate use of alcohol.

Slow pulse, or bradycardia, is a term applied to cases in which the pulse falls, according to some authorities, below 60 per minute, or according to other writers, below 40. Slow pulse should be regarded as a symptom only. It may be due to a variety of causes. Bradycardia should be limited to such cases in which the infrequency of the pulse is due to a disorder of innervation. A slight reduction in the frequency of the pulse is common in disturbances of the digestive tract.

In paroxymal tachycardia the attack is always sudden in onset, and usually unexpected. The pulse is increased from normal to from 180 to 240 per minute, or even to 300 per minute, according to some observers. There is no disturbance of rhythm and no intermittence. The heart beats in a strong and energetic manner, and in direct contrast to its action is the extreme diminution of arterial tension. The cessation of the attack is as sudden as its onset. The paroxysms vary in duration from a few minutes to several hours, and occasionally last even for days. The intervals between the attacks are irregular. During an attack the excretion of urine is generally diminished; it may be followed by the passage of a large quantity of clear, limpid urine. The etiology of these cases is obscure. Psychic influences, fright, errors of diet, bodily exertion, have all been assigned as causes. Tachycardia is an affection of adult life, and the best established causes are bodily and cerebral overwork. In these cases it seems probable that the condition is a bulbar neurosis.

DR. J. W. BRANNAN said that some years ago, when he made a study of the pathology of tachycardia, he was inclined to believe that the condition was due to a bulbar neurosis, but he afterward rather favored the suggestion that the cause of the trouble was to be found in the heart-muscle. Up to four years ago, only four autopsies were recorded, and in all of these the nervous system was found intact; in only two was the heart-muscle examined, and in both cases an extensive development of fibrous tissue was found in the wall of the left ventricle. This may have been due to the rapid action of the heart. In another case, in which the disease had existed for only three months, there was an extensive development of fibrous tissue throughout the wall of the left ventricle, in the trabeculæ, and the papillary muscles. The only objection to this theory lies in the fact that there are so many cases of myocarditis without any history of tachycardia. This has been accounted for by the explanation that certain portions of the heart-muscle are tolerant, while other portions are intolerant, and involvement of the latter gives rise to tachycardia. The intolerant regions are especially found in the inter-ventricular wall and the papillary muscles.

DR. HERTER referred to a case of paroxysmal tachycardia in a man who is a sexual neurasthenic, and suffers from intestinal indigestion. Each attack lasts four or five hours, and is generally induced by some indiscretion in diet. The urine passed after such an attack contains in large amount the products of intestinal putrefaction. It is an interesting question whether the attacks are due to these poisonous substances, or perhaps to mechanical causes—such as distention of the colon, or other parts of the intestinal tract.

Susceptibility to Homatropine.—A correspondent writes us concerning a case almost identical with that published in THE NEWS, January 21, p. 78.

NEWS ITEMS.

Hardy, the distinguished French dermatologist, died recently.

The New York Therapeutic Review is the name of a new quarterly edited by Dr. Paul Gibier, who will be supported by a notable list of collaborators.

The Philadelphia Neurological Society.—A stated meeting will be held February 27, 1893, at 8.15 P.M. Dr. C. L. Dana, of New York, will read, by invitation, a paper entitled "Some Studies of the Nature and Symptoms of Shaking Palsy, with the Report of an Autopsy."

The Eleventh International Congress of Medicine will be inaugurated in Rome on the 24th of September, 1893, and will close on the 1st of October.

Any physician may become an active member of the Congress by fulfilling the conditions of membership, inscribing his name, and securing his admission ticket.

Scientists of other professions, who, through their special studies, are interested in the labors of the Congress, may acquire the rights and assume the duties of active members, and participate in the work of the Congress, both by communications and discussions.

The fee for admission to the Congress is twenty-five francs, or five dollars.[1] It entitles to a copy of the *Transactions* of the Congress, which will be forwarded to the members immediately after publication.

The character of the Congress is strictly and exclusively scientific.

The work of the Congress will be divided amongst nineteen sections; every member is requested to indicate, on paying his admission fee, the section in which he desires to be inscribed.

The provisional committee will arrange the appointment, in the opening session, of the permanent officers. They will be a president, three vice-presidents, a number of honorary presidents and secretaries. Each section will elect, at its first meeting, its president and a certain number of honorary presidents, who shall alternately take the chair during the session. Some of the secretaries will be chosen from among the foreign members, in order to facilitate the recording both of communications and of discussions in the different languages.

There will be daily sessions, either general or sectional. The times and number of the general sessions, and the business to be transacted in them will be arranged by the President of the Congress.

The general sessions are reserved for (*a*) the consideration of the common work of the Congress and of its common interests, (*b*) addresses and communications of general interest and importance.

The addresses in the general sessions, and in such extraordinary sessions as may be arranged, will be delivered by members chosen by the committee for the purpose.

Papers for and communications to the Congress must be announced on or before June 30, 1893. A brief abstract of every paper and communication, with their conclusions, must be sent to the committee on or before July 31st. All of them will be printed and distributed to the members, by authority of the President. Such as arrive after that date cannot be expected to find a place on the regular order of business, and will be accepted only if time will permit.

The business of the sections will be arranged by their presidents, who will also determine the hours of meeting, avoiding those reserved for the general sessions. Two or more sections may hold joint meetings with the consent of their presidents. There will be no vote on scientific questions.

Fifteen minutes are allowed for the reading of a paper or communication. In the discussion every speaker can have the floor but once, and for five minutes only. To close the discussion the author of the paper is allowed ten minutes. Additional time may be given him by the president, by special resolution of the section, if the importance of the subject under discussion appear to require it.

The manuscript of all addresses, papers, and communications read either before a general session or a section must be handed to the secretary before the close of the meeting. A special committee on publication, appointed by the president, will decide which or what part of them shall be published in the *Transactions* of the Congress. Such members as participated in the discussions are required to hand to the secretaries their remarks, in writing.

The official languages of the session are Italian, French, English and German. The regulations, programs and daily bulletins will be published in these four languages. During the meetings, however, a member may be permitted to use, for a brief remark, any other language, provided some member present expresses his willingness to translate such remarks into any of the official languages.

The president directs the discussion according to the parliamentary rules generally obeyed in similar assemblies.

Persons not classified under Article 3, who are interested in the labors of a special section, may be admitted by the President of the Congress. They will receive a special ticket on paying their admission fee; will not be entitled to a copy of the *Transactions*, and cannot speak in the general sessions or in any section other than that for which they were inscribed.

The President may invite or admit students of medicine to attend and to listen. They will be given a special admission ticket, free of charge.

Arrangements have been made with the different Italian and foreign railway and navigation companies, in pursuance whereof special reduced prices have been granted on the steamers and railways of the countries which the members of the Congress are to traverse.

On the occasion of the Eleventh International Medical Congress, an Exhibition of Medicine and Hygiene will be inaugurated in Rome, which will gather all that may practically interest physicians and specialists.

[1] Money order or check to the treasurer, Professor Comm. L. Pagliani, Rome, Italy. Dr. A. Jacobi, Chairman of the American National Committee, 110 West 34th Street, New York, has volunteered to forward applications and fees.

SOME RECENT CASES OF APPENDICITIS.[1]

BY NATHAN JACOBSON, M.D.,

PROFESSOR OF CLINICAL SURGERY, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY; SURGEON TO ST. JOSEPH'S HOSPITAL, SYRACUSE, N. Y.

IN presenting a few cases of appendicitis, which it has been my fortune to have recently seen, it is not my purpose to consider in detail this most important pathologic condition. Nor can I hope to place before this Society any facts which may be new. My object is rather to add my observations to existing data. For out of the accumulated experience of all must develop the true pathology and treatment of appendicular disease.

With the presentation, in 1886, of the result of his investigations into the pathology of the appendix, to the Association of American Physicians, Fitz established a new era in our knowledge of these conditions. Since Morton, in the spring of 1887, deliberately cut down upon and successfully removed an ulcerated appendix, and the equally successful undertaking of Sands at the close of the same year, the surgical treatment of the diseased appendix has been completely changed.

The subdivision of appendicitis into many forms only serves to obscure a proper conception of the condition, and render more difficult a decision as to the proper treatment. In a large majority of cases inflammation of the vermiform process is of the catarrhal type, terminating without suppuration. It is not easy to determine with mathematic accuracy what percentage of cases belongs to this class. It has been variously stated that it would include 80, or possibly 95 per cent. This large group would embrace those to be treated by medicinal measures. No one would recommend operative interference for them.

The very fact that such a large number of cases is quite certain to recover in the hands of the physician makes it all the more necessary that he be on his guard not to include among them a single case that might ultimately demand surgical treatment. To determine what cases are to be treated medicinally and those that should be treated surgically will often tax the ingenuity and skill of the physician. I shall deal in this paper only with such cases as may be suitable for surgical measures. To this class belong, first of all, cases in which the inflammation reaches the suppurative stage. As types of the suppurating form, not involving the peritoneal cavity, I desire to refer briefly to two cases:

CASE I.—On the 29th of January, 1892, I was requested by Dr. Breese, of Syracuse, to see with him a man, forty-one years of age, a machinist, with a negative family history, who, twenty-five years previously, had had typhoid fever, and five years later smallpox. He stated that he had had numerous bilious attacks. Preceding these, there would always be pain in the right iliac fossa. This pain would be severe enough to make walking difficult. It would increase in intensity until it prostrated him. Nausea and fermentation of food in the stomach would occur, and he would ultimately be relieved by free emesis and evacuation of the bowels. As long as twenty years previously he recalled having had a tumor form in the right iliac region, which ultimately disappeared. On the 1st of January, 1892, his pain reappeared, but he kept about until the 16th of the month, each day finding walking more difficult, and the pain more severe. A tumor, steadily increasing in size, appeared in the right iliac fossa during the two weeks preceding my visit to him. There was constant fever. The bowels moved once daily. There was anorexia and nausea, but no vomiting. I found very extensive tumefaction, reaching well down to Poupart's ligament, upward as high as the level of the umbilicus, and internally for a distance of three inches. Rectal examination revealed the presence of a tumor. His hygienic surroundings were very poor, and the prospect of care at home no better. He was, therefore, sent to St. Joseph's Hospital on the following day. Upon his arrival we found that during the preceding night there had been a spontaneous rupture of the abscess into the rectum, and all evidence of tumor had disappeared. Pus was discharged for a period of five days, after which the patient's local and general condition constantly improved, and he left the hospital on the 18th of February, thoroughly well.

The statement is usually made that recurrent forms of appendicitis rarely lead to suppuration. This is, I believe, by no means the rule. In this case, I take it, we are obliged to regard his so-called "bilious attacks" as manifestations of recurrent appendicular inflammation. It has been recently said that rectal examination is very valuable in determining at an early period the presence of disease of the appendix. For myself, I have only encountered it very late. Lange and others have operated upon this form of abscess, which the Ger-

[1] Read at the meeting of the New York State Medical Association, November 15, 1892.

mans prefer to call paratyphlitis, by incision through the rectum, with, as a rule, a successful termination.

CASE II.—H. C. H., thirty-eight years of age, was seen in consultation with Dr. J. L. Heffron, July 14, 1892. During the previous winter the patient had been seriously sick with typhoid fever, from which he seemed to have made a very satisfactory recovery. At various times during the past few years he had attacks of severe pain in the right side of the abdomen, associated with nausea and constipation. Nine days prior to my visit he had been seized with severe pain in the bowels, located well down in the right inguinal region. The bowels had moved daily by administering one dram of Rochelle salts each morning. Tympanites was controlled by intestinal antiseptics. Heat applied did not relieve the pain, and was irksome to him. The temperature had been well down, although at my visit it reached 102°. The pulse had usually been about 80. His pain was not at all severe, nor did he really feel sick. After the fifth day a tumor could be mapped out, reaching along the brim of the pelvis from the anterior superior spinous process downward three or four inches. It was very firm, did not fluctuate, and was not at all tender. Neither the condition of the patient nor the tumor seemed to demand active interference. I did not see the patient again until November 22d. There had been a daily rise of temperature. The thigh was drawn upward, and rotated inward. The tumor had grown rapidly in size, was very tense—in fact, too tense to permit the recognition of fluctuation. Immediate operation was advised, and under ether the abscess was freely opened by an incision running one inch above and parallel to Poupart's ligament from its outer third up to the anterior superior spinous process. In carrying the incision into the depth, the peritoneum was incised for the distance of an inch, the omentum protruding. This was speedily closed with catgut sutures. It was estimated that nearly a pint of pus was discharged. The wound was thoroughly irrigated and packed with iodoform-gauze. Daily irrigation with a sublimate solution, and packing with iodoform-gauze, were kept up. The closure of the wound has been very slow, and in fact at this late day there still remains an unhealed sinus with a depth of about one and a half inches, and a transverse diameter of one-quarter of an inch. The general health of the patient has steadily improved, but mentally he is greatly depressed because of his tedious convalescence.

This case is another example of suppuration occurring in a chronic relapsing appendicitis. The vermiform process probably had melted away in the course of the suppurating inflammation. The abscess-cavity, with its thickened walls, evidently stood in the way of prompt repair, and subjected the patient to the annoyance of very tardy recovery, and the possibility of a permanent sinus.

CASE III.—As very strikingly opposed to the slowly-forming pus-collections which are hemmed in by adhesions, and from which the peritoneum is thus protected, I desire to report the history of a patient seen with Drs. Elsner and Didama, October 3, 1891. He was unmarried, twenty-three years of age, a candlemaker. He was very vigorous, and since childhood had never required any medical attendance. On the morning of October 22d he had gone to his work as usual, but at 10 o'clock called upon Dr. Elsner, complaining of pain in the abdomen, which upon examination was found to be distended, rigid, painful on pressure, particularly so at the McBurney point, two inches from the anterior superior spinous process, on a line drawn to the umbilicus. It was learned later, that on the preceding day he had been obliged to return home from his work because of abdominal pain, but finding relief from medicine administered at home, he resumed his work. When first seen by Dr. Elsner the temperature was normal; yet the diagnosis of appendicitis was made. Within twenty-four hours the condition was greatly aggravated. There was constipation, increasing pain, some vomiting, general peritonitis; temperature 102.5°, pulse 96. In the afternoon, when seen by myself, together with Dr. Elsner, it was decided to perform celiotomy. The patient was properly prepared with the usual precautions. An incision along the outer border of the right rectus abdominis muscle was made. There was but little bleeding. Upon incising the peritoneum thick yellow pus appeared. The wound was enlarged, and the cecum exposed. Upon its surface were thick adherent flakes of pus; the omentum was not gangrenous, but partly thickened, and some pus was in the iliac fossa. The appendix was reached without difficulty, lying to the outer side of the cecum, adherent to the surrounding tissues, but easily separated. It was thickly infiltrated, darkly discolored, and upon its free extremity presented a gangrenous ulceration. There was no perforation, nor did it contain any concretion. It was one and three-quarters inches long. After ligation it was cut off, its surface cauterized with concentrated carbolic acid, the diseased surfaces were touched with a strong sublimate solution, a drainage-tube was inserted, around it the packing of iodoform gauze, and the wound partially closed. After the operation the pulse was 130. At 10 P.M., patient was resting quietly. The pulse, however, had gone to 150, the respirations to 30, the temperature to 102.8°. The patient had not urinated voluntarily during the entire day. The following morning the nurse reported that the patient had passed a quiet night. At 10 in the morning the temperature was 102.8°, pulse 130, respirations 30. At 3 P.M. a marked change suddenly came over the patient. The temperature shot up to 105.5°, his pulse to 160; his respirations became shallow; muttering delirium and great depression appeared. When seen by me at 6 P.M. he was unconscious, the pulse flickering, and an hour later the patient was dead.

This very rapid development of ulcerative appendicitis, awakening almost from the outset a septic peritonitis, without any previous manifestations of

disease of the vermiform appendix, is very unusual. That a person should have continued his work after a peritoneal inflammation had developed, and not have presented himself to a physician for treatment, hardly seems possible.

The period at which an operation is performed is not to be designated as early because a few hours or even days have elapsed since the patient has presented himself for treatment. This period cannot be measured by any supposed period of time. An early operation is one performed while the disease involves only the appendix. If peritonitis is present, it matters little whether for its development it has required one hour or one week. The complication is equally serious in either event, and the operation, no matter how soon performed after the appearance of septic peritonitis, is no longer to be regarded as an early operation. Dr. Jacobi has made a very happy exchange of terms by suggesting that operations, to be successful, must be not only early, but timely. Very few cases have recovered in which septic peritonitis has coëxisted. Recently, however, Abbe has reported the successful termination of some of his operations, by making a second incision upon the left side of the abdomen, and in this way establishing thorough irrigation.

CASE IV.—February 10, 1892, I was called by Dr. E. A. Didama to Cortland, N. Y., to see a young man, aged twenty-seven. The patient had never been seriously sick, but for several months complained of a "pain under the ribs" on the right side, on exertion. There never had been an acute attack of pain or fever. He had felt usually well until the morning of the 8th, when he was seized with pain so severe, which he referred to the epigastrium, that he was obliged to stop work. There was only slight elevation of temperature, but great pain and constipation. An anodyne was administered. On the following day the pain was intensified, and it was necessary to administer morphine hypodermatically. On this day vomiting set in. On the 10th the symptoms were aggravated, the pain being localized in the right side. He was unable to retain either food or medicine administered by the mouth, and under the influence of a mercurial cathartic the bowels moved loosely several times. One movement in the afternoon, which contained solid fecal matter, relieved the patient considerably. At 1 in the afternoon the temperature was 102.5°, the pulse 102. When seen by me at 3 o'clock the temperature was 101°, pulse 110, respiration rapid and shallow. Both limbs were extended, and the patient moved about in bed with great pain. The entire iliac region was exceedingly sensitive to the touch, and the abdomen was slightly distended. Along the outer iliac fossa dulness existed for an area one inch in breadth. No tumor could be felt. The most tender point was one and one-half inches from the anterior superior process, on a line to the umbilicus. The patient felt somewhat improved, but the persistence of the local signs led me to advise celiotomy. Assisted by Drs. Didama and Higgins, of Cortland, after a hasty preparation of the patient, I made an incision, four inches in length, along the linea semilunaris. Upon incising the peritoneum, a stream of thin pus appeared. The appendix did not readily come into sight, but was discovered by my finger, external to and behind the cecum, extending upward, and adherent throughout its entire length. It was greatly thickened, infiltrated, darkly discolored, purple at its terminal extremity, and for a distance of one and one-half inches gangrenous near its attachment to the cecum. With some difficulty it was detached, and dissected well out to the cecum. The parts were sponged out with an antiseptic solution, the intestines protected with sponges, the appendix drawn up, ligated with silk at its base, and after tying its mesentery, removed. It was found to be six inches in length, distended with a quantity of thin pus, and contained no less than one dozen firm concretions of fecal character. The cut surface was cauterized with carbolic acid, the cavity was thoroughly mopped with a sublimate solution 1 to 1000, a drainage tube introduced, surrounded with a packing of iodoform-gauze, and the wound partially closed at its upper extremity. He rallied promptly from the operation, and two hours later the temperature was 98.5°, and the pulse 78. He slept fairly well during the night, and a change of dressings was made early the next morning. The patient still remained free from fever, and though suffering at the time of dressing, was otherwise free from pain. Word was received on the 13th of the patient's continued improvement, and the statement made that apparently nothing could interfere with his recovery. Shortly before 10 o'clock on the evening of the 15th, I received a message calling me immediately to Cortland. On that evening the patient had suddenly developed a rise in temperature, and great pain in the iliac fossa recurred. The bowels had moved daily, and there had been substantially no discharge from the wound. Anesthetizing the patient, I made an examination of the wound, and found some adhesions at the surface. Beneath the superficial adhesions there was a small quantity of pus, and on displacing the head of the colon, a stream of liquid feces appeared. Cleansing the wound as well as possible, an examination showed a perforation into the cecum, close to the appendicular attachment. Its edges were promptly denuded, inverted, and the wound closed with a Lembert suture.

The patient rallied nicely from this operation, but gradually sank from the development of a septic peritonitis, and died on the 20th of February.

The very promising course of this case in the early days following the operation had led us all to look forward, with apparently good reason, to a happy termination; but despite the irrigation of the wound with antiseptic solutions, and the subsequent careful packing of iodoform-gauze by Dr. Didama, the septic inflammation led to the perforation of the cecum.

CASE V.—September 24, 1892, I was called by Dr. C. S. Roberts to see J. M., aged twenty-one years, a butcher, unmarried, strong and robust, for the purpose of relieving what was supposed to be strangulated hernia. The patient was said to have had a right indirect inguinal hernia, which, when protruded, would return by lying down and keeping quiet for a short time. On the evening of the 22d he lifted a heavy quarter of beef, and was speedily seized with pain in the abdomen. During the night the pains assumed great severity, and were restricted to the region of the umbilicus. On the morning of the 27th he was given two large doses of salts. His bowels had moved on the previous day, but did not respond to the salines. The pains increased in severity, and Dr. Roberts, being called, administered an opiate, without relief. A soft elastic tumor existed in the upper portion of the right side of the scrotum. Taxis was applied, and also heat, but ineffectually. The patient was put upon his back, with thighs elevated, and resting upon a chair. In this position I found him at 4 P.M. on the 24th of September.

Examination of the tumor revealed an elastic swelling the size of a small hen's egg. The spermatic cord could be felt above and below. The abdomen was not distended, but was exceedingly rigid. The tongue had a dry, brown central streak. The pulse was 80, the temperature 100.5°. Upon pressure the entire abdomen was tender, but the pain was particularly upon the right side, and tenderness to digital pressure most marked at the McBurney point. The opinion was expressed that whatever the swelling in the scrotum might be, it had nothing to do with the abdominal trouble, which was believed to be the beginning of general peritonitis, dependent upon appendicitis. Celiotomy was advised, and, assisted by Drs. Roberts and H. D. Didama, was undertaken in the usual way. The incision was made along the outer border of the rectus abdominis muscle. After controlling the hemorrhage, which was slight, the peritoneum was opened. No pus was found. The appendix was concealed in a mass of adhesions. From these it was carefully separated, and was found to be one and one-half inches in length, thickened, almost purple in color, its surface in a condition of gangrenous inflammation. Near its base it was constricted and bent upon itself. It was ligated at its base, severed, and its cut end cauterized with carbolic acid. Every part was fully washed, and as there had been no pus present the wound was carefully closed by suture. It was now thought advisable to examine the scrotal swelling. An incision over it soon exposed an encysted hydrocele of the cord. This was split open, stitched to the surrounding skin, and packed with iodoform-gauze.

In the evening the urine, which had been retained for twenty-four hours, was drawn with a catheter. He passed a very restless night, but suffered more from the cystic than the abdominal operation. On the following day the temperature was 101.5°, but the tongue was less dry and the abdomen was less tender. There was no vomiting, and the bowels remained constipated. By the 28th of September all evidences of peritoneal inflammation had disappeared, and from this time the patient made an absolutely uninterrupted recovery.

In this case the timely removal of an appendix, beginning to be gangrenous, arrested peritoneal inflammation, and resulted in a very happy recovery. I believe a delay of twenty-four hours would have placed the patient beyond operative relief.

CASE VI.—C. W., aged forty, married, was seen September 9, 1891. He had usually enjoyed good health, but early in May last, while at Baldwinsville, he was seized with pain in the right side of the abdomen, with nausea, fever, and constipation, and was confined to his bed for one week. During the latter part of July a similar attack confined him to his bed for a few days. Two days previously the third recurrence manifested itself. During the months that had intervened there had been more or less constantly present a tender spot on the right side of the abdomen, which frequently interfered with locomotion. An examination showed a very slight tumor. Tenderness to finger-pressure was marked at the McBurney point. There was persistent nausea, but no vomiting. During the following week the patient was kept abed, although the acute manifestations disappeared about the 14th of the month. All that remained was a slight dulness along the outer border of the iliac fossa, and a little induration just above the level of the anterior superior spinous process. The patient, who had become greatly depressed because of the three recurrences of the inflammation of the vermiform appendix in the course of four months, very readily consented to the suggestion that the appendix be removed. On the 20th of September, 1891, he was removed to St. Joseph's Hospital, Syracuse, and on the following day, assisted by some of the gentlemen of the hospital staff, after the usual preparations, I made an incision into the abdominal cavity, as heretofore described, and after a little difficulty discovered the appendix adherent on all sides to the outer and posterior portion of the cecum. It was an inch and three quarters in length, densely infiltrated, and constricted at its base. Protecting the peritoneal cavity with sponges, it was removed by the knife, and its base cauterized with the Paquelin cautery. The abdominal wound was closed. There was nothing to mar the patient's recovery, which proceeded in every way satisfactorily. In the fourteen months which have elapsed since the operation, the patient has not had the slightest suggestion of a return of the previous symptoms, and has improved so much in his general condition that, to use his own words, "he feels quite like a new being."

The cases presented form an excellent text for the discussion of the surgical treatment of appendicitis, inasmuch as they present the various surgical aspects of the disease. But as I have already occupied so much time, I prefer to briefly summarize

the propositions I have to offer, and put them in the form of a series of conclusions, based not only upon my own cases, but upon the accumulated experience now at the disposal of the profession.

CONCLUSIONS.—1. As the appendix, and not the cecum, is the primary seat of disease, these forms of inflammation should be known as appendicitis. The terms typhlitis, perityphlitis, and paratyphlitis are not only confusing, but incorrect.

2. It is most important to determine whether the inflammation is non-suppurative or suppurative. If suppurative, it is equally vital for proper treatment to establish whether the diseased appendix and the purulent collections are to be hemmed in by protective adhesions, or to remain in direct communication with the general peritoneal cavity.

3. With symptoms of moderate severity, and no tendency of the inflammation to increase in extent or severity, but rather to decrease after thirty-six hours, it is safe to treat the case medicinally.

4. The exhibition of salines or other cathartics, in the early stage of appendicitis, is not only inadvisable, but likely to interfere with the development of protective adhesions, and may even be responsible for perforation. Exploration with the needle to determine the presence of pus is useless, and may be dangerous.

5. The violence of symptoms, and their continuance and progression, indicate the presence of existing suppuration, and render operative interference justifiable. The earliest manifestations of a developing general peritonitis make immediate operation absolutely imperative.

6. Each case is to be considered in the light of the individual symptoms it presents. The absence of fever should not lull the medical attendant into a belief of security. The proper moment for operative intervention in a given case cannot be established by the period of time elapsing in its development. Timely operation implies its performance before the appearance of septic peritonitis or other serious complications.

7. When the inflammatory process is of moderate severity, and evidence of tumor-formation is present, operation can be delayed until the fifth, or even as late as the twelfth day. The incision then to be made is to begin parallel with Poupart's ligament, an inch above its center, and curves upward along the outer border of the iliac fossa, and is thus to be entirely extra-peritoneal.

8. Acute cases, manifesting signs of perforation or gangrene, with no evidence of protective adhesions, demand immediate operation, the incision to be carried along the outer border of the rectus abdominis muscle, and directly into the free peritoneal cavity.

9. Advanced cases of suppuration, in which the abscess is post-cecal, can be opened by rectal incision.

10. Patients in whom attacks of appendicitis persist in recurring, especially when localized tenderness continues, should submit to the removal of the appendix during an intermission.

DURATION OF LIFE OF THE NERVOUS AMERICAN.

BY JULIUS POHLMAN, M. D.,
PROFESSOR OF PHYSIOLOGY, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO, N. Y.

EACH nation seems to delight in emphasizing some one of its native peculiarities. We speak of the pugnacious Irishmen, the mercurial Frenchman, the patient German, the singing Italian, etc., and representatives of all these different people, placed upon an immensely rich but undeveloped continent of vast dimensions, have in their mixture produced the rushing American. And as we have learned that rapidity of action means rapidity of thought, and that this again means a corresponding expenditure of nervous energy, and as we have seen many strong men break down in the prime of life from overwork, we have, by common consent, looked upon the nervous American as the type of the citizen of our great republic to-day.

True, everybody deplores the fact, but confesses that it can't be helped, and finds consolation in the old saying that it is better to wear out than to rust!

Even such man as Prof. Thomas A. Emmet[1] tells us that—

> "Rest and recreation in the European sense are unknown to the mass of our population. We develop early and live a life crossed by more than our share of dyspepsia, neuralgia, and other nervous disorders. . . . . Our field of education is as extensive as, if not more so, than that of our neighbors, but it is more superficial; . . . the same mental application on which a German in his own land would thrive will in this country impair the physical condition or result in some serious nervous disorders."

And then we read every once in a while of some well-known, successful business or professional man who had to be sent to the insane asylum, and writers and orators find a convenient chance for the flow of eloquent and soul-stirring language to show how the present fearful rate of speed at which everything is done here in the struggle for existence begets this increasing nervousness, with its necessary reaction upon the body, and how the constant hurrying and driving in our daily work mean a corresponding shortening of life, or, if not death, then some form of insanity as "again demonstrated in the case of our dearly beloved fellow-citizen," etc.

And we read such statements and are convinced! We calmly accept the questionable dis-

[1] Principles and Practice of Gynecology, p. 18.

tinction as a fact. We know it is so! We know that Americans wear out faster and die earlier than the more phlegmatic Europeans, because we do everything under a higher pressure and at a higher speed. It makes us feel so delightfully miserable, so wretchedly proud to know that Americans are such a nervous lot and such a rapid-living nation! It is such a convenient excuse for so many of our individual shortcomings!

If it were merely a matter of terms, tickling our national vanity, we might pass it over with a smile, but side by side with the idea of "nervousness" rides the grim specter of shortened life, of premature but preventable death striking terror to the hearts of thousands, who watch with anxiety the struggles and efforts of their beloved ones—men, women, children, business or professional men—all are interested in this question more or less, and it well behooves us to ask: Is this so-often-quoted "fearful nervousness" and "early death" a fact, or merely an assertion? What proofs have we for it?

It seems very plausible indeed, and apparently correct physiologic reasoning to say that the individual's longevity is in inverse proportion to his daily hurry, all other things being equal. But until not many years ago the equally misleading but equally plausible statement was accepted, that the human race was growing smaller with the advance of civilization. It seemed so self-evident, indeed, that in the past, when men had nothing to do but to develop their muscle, when very little or no energy was used in educational problems, the body would be larger than at present, when the cultivation of the mind absorbs so large a share of our strength, and when so little attention is given to physical development! Everybody believed it then, large numbers of people believe it to-day, and yet scientific investigations have conclusively demonstrated the fallacy of that assumption.

First of all, the assumption that increased activity and greater hurry mean more rapid wearing away of the body ignores the fact that the human body is a wonderful piece of machinery which not only renews itself constantly, but whose strength and power of endurance and capacity for more work increase with increased use up to the point at which use becomes abuse. At what time and under what pressure this danger-line is reached depends upon the individual, and need not be discussed here, but under all conditions the physiologic law holds good which says that the strength of the organ is determined by its use, whether applied to the brain or the foot, to intellectual work or to physical labor.

To prove that Americans live as long as other nations is not an easy task; general statistics may well be excluded here when we remember the ease with which the same figures can be made to prove opposite problems. The only statistics that could be considered fairly reliable here are perhaps those of life insurance companies doing business in America and Europe; and a comparison of premiums charged under similar conditions on both sides of the Atlantic will furnish us with at least a few useful data. If the European's lease of life is longer than that of the American, then the insurance company will insure him at a smaller premium than his American brother, and if the latter wears out faster, it would be a suicidal policy for any life insurance company to insure him at the same premium at which the risks are taken in Europe on Europeans.

The executive officers of the Equitable, the Mutual, the New York, and the Germania life insurance companies have kindly supplied me with the following information:

The *Equitable* writes as follows: Our rates in Europe are the same as in the United States. In some parts of Europe we charge more, but it is not so much on account of the fear of extra mortality as on account of the onerous conditions under which we are compelled to do business.

The *Mutual:* The experiences of British and German companies show that the lives which were insured in those companies were not on the average as good as the lives insured in American companies. The experience of this company is thus far quite as favorable on its European business as on its business in this country.

The *New York:* The rates charged in most parts of Europe and England are the same as those charged under similar conditions in this country.

The *Germania:* Our premiums are higher in Europe than in America.

These four companies insure together about 550,000 lives in America and about 65,000 in Europe; a limited number, true, but they all tell us unanimously that from the material standpoint of dollars and cents the life of the American is at least as good, if not better, than that of the European, all other conditions being the same. And if we remember that probably the majority of the holders of policies of life insurances in this country is made up from those very same active, pushing and rushing men, a class among which "death from overwork" would naturally occur most frequently, then the figures mentioned acquire additional force. Based upon that most sensitive spot of the human anatomy, the pocketbook, they permit of no sentiment, no public opinion, no emotional eloquence, but calmly proclaim in cold hard figures that the chances for a long life are just as good in America as they are in Europe.

Mr. Herbert Cillis, the actuary of the Germania Life Insurance Company, has kindly furnished me with a compilation drawn from every available source regarding the estimated duration of life at

different years of age, both in America and Europe, of which the following is a short abstract:

Age.	Estimated duration of life in America.	England.	Germany.
11	48.72	50.29	.....
12	48.08	49.54	.....
13	47.45	48.73	.....
14	46.80	47.89	.....
15	46.16	47.03	.....
16	45.50	46.16	.....
17	44.85	45 29	.....
18	44.19	44.44	.....
19	43.53	43.61	.....
20	42.87	42.82	.....
21	42.20	42.06	40.45
25	39.49	39.15	37 42
30	36.03	35.42	33.62
35	32.50	31.75	29.89
40	28.90	28.12	26.26
45	25.27	24.51	22.77
50	21.63	20.99	19.39
55	18.09	17.62	16.20
60	14.10	13.83	12.76
65	11.10	11.01	10.21
70	8.48	8.50	7.96
75	6.27	6.38	6.03
80	4.39	4.72	4 42
85	2.77	3.51	3.30
90	1.42	2.36	.....
95	0.50	0.93	.....

These figures certainly show that, as far as life insurance statistics go, the chances of the American, from early manhood to a good old age are, all through, a little better than those of his English brother, and a good deal better than those of the Germans, in spite of all statements about "climate" and "nervousness." If, between the ages of twenty and seventy, life insurance companies, based upon dollars and cents, allow the Americans a longer life right through, then it seems that we are justified in concluding that we have simply obeyed the old physiologic law and adapted the machinery of our body to a high speed without hurting ourselves, while our European brethren dodge along at a low pressure without, on that account, prolonging their life.

But the foregoing tables teach us something more. At eleven years of age the chances of the American boy are *1.57 years less* than those of his English brother. It is a pity that the statistics do not deal with younger children, but we may well pause to grasp the full meaning of this statement, for it involves a heavy accusation against American motherhood, and unfortunately against the mothers of the better classes, because the poor people rarely, if ever, insure in the regular companies. We may well raise the question: Is the American woman a less capable mother than her English sister? Has she, in her striving for fashionable fads and foibles, for literary crazes, women's advance clubs and political organizations, ignored or neglected or forgotten the first and most important function of a woman, the duties of motherhood? Is it carelessness or over-care, indolence or ignorance, that gives to the English boy at the age of eleven 1½ years more of life than to the American boy (for these tables are all based on figures for the masculine gender). The latter improves from year to year, as he grows away from mother's care, or carelessness, as the case may be, so that at the age of twenty his chances are as good as those of his transatlantic brother, and the question that presents itself very forcibly is: What is the cause of this high rate of mortality of our children? Don't let us crawl behind that well-worn excuse and say "It is the climate." And if the climate *has some* influence, let us try and find out how much, and at the same time investigate the other factors contributing toward that end.

This paper is merely intended as a preliminary study of a subject of general interest: may it call forth other additional investigations and help, not only in breaking down the dangerous popular fallacy that the rushing American is doomed to an early grave, but also aid in discovering ways and means by which the present abnormal death-rate among American children can be reduced to more normal figures.

CLINICAL LESSONS.

CHOREOID MOVEMENTS IN AN ADULT MALE, PROBABLY OF HYSTERICAL ORIGIN; RELATIONSHIP TO HABIT-CHOREA.

Clinical Lessons:
Infirmary for Nervous Diseases of the Orthopædic Hospital.

BY S. WEIR MITCHELL, M.D.,
OF PHILADELPHIA.

[Reported by CHARLES W. BURR, M.D.]

D. F., a white male, thirty-seven years of age, applied for treatment December, 1891, on account of spasmodic to-and-fro movements of the head. The family history is negative, and the previous health has been generally good. He had typhoid fever when ten years old, and again when eighteen. He has been married fourteen years, and had had three children, of whom one died of dysentery. Syphilis is denied and there was no evidence of it. His habits were good, and he did not use tobacco excessively.

About three months before coming to the Infirmary he had been much worried about moving his place of business to some other part of the country. He could reach no decision, grew very nervous, slept very little, became dyspeptic and very melancholy. After about two weeks spasmodic movements of the head suddenly appeared.

Present state. Every few moments the head is forcibly jerked backward by the trapezii muscles. When lying in bed the spasm is much less frequent. It is

increased in frequency during examination, and for a time ceases entirely if the attention be strongly directed to any object. For example, while looking at a thermometer bulb, the patient was quiet for five minutes. During sleep there are no movements whatever. While in the hospital he developed general choreiform movements.

He is fairly well nourished. His expression is markedly melancholic. Intelligence is good, but he is profoundly apathetic. He declares that he sleeps very little. His appetite is poor and he suffers much from gaseous eructations after eating. The thoracic and abdominal organs are normal, the station good, and the gait normal. The urine is normal. Prof. de Schweinitz examined his eyes and reported slight hypermetropic astigmatism with insufficiency of the interni.

The patient was put at absolute rest in bed, given gelsemium, bromid, and chloral, and given, later, hypodermatic injections of distilled water. These had a very happy effect upon his insomnia, and, indeed, caused drowsiness the following day. After about eight weeks' stay in the hospital he was discharged greatly improved, but still having occasional clonic spasms of the trapezii. There were no sensory changes. The man was emotional and given to tears. Soon after admission he began to have at times, after exercise, great emotion, or any excitement, spasmodic jerks of one limb, or of the trunk. Thus the arm would be extended forcibly, and again and again for a half-hour, or the leg, or both legs; or he flopped fish-like until wearied. The head-movements were likely to cease when any other form of spasm was present, but were, on the whole, the most common. They were generally either to-and-fro motions or backward jerks, seemingly due more to the trapezii than to the other posterior neck-muscles. Over all of these movements he had temporary volitional control. When he thus restrained them he said that the sense of weariness became by degrees unendurable and he had to let go.

REMARKS.—The resemblance, clinically, to the cases of habit-chorea or habit-spasm, as Gowers likes to describe the disorder I first called attention to some years ago, is very striking. The lad I shall show you to-day is another illustration of a genus of cases which has several related species, and all that variety which individuality occasions. As in this case and in that of the boy, hysteria is the potent agent in their production.

Acute habit-chorea, resembling so-called electric chorea.—B. F., a male, ten years of age, applied for treatment in December, 1892, complaining of involuntary movements of the head. His father had had fits in childhood, and one cousin has had habit-chorea. One brother died in convulsions when seven months old. The patient had diphtheria when two years old, scarlet fever three years ago, and measles last year. He has always been nervous. The mother states that he is the smallest boy in his class and has always stood at the head in his studies. She thinks that over-study in preparing for examinations may have been the cause of his illness. The present trouble began about two weeks before application for treatment.

There is constant wagging of the head from side to side, shrugging of the shoulders, and winking. The patient is a bright, well-made lad, with excellent muscular development. There is no ataxia of motion or station. The knee-jerks are capricious. Clonus is absent. The cremasteric reflex is present. The abdominal reflexes are absent. The elbow-jerk is present. The muscle-jerks in the arms are very marked. There are no palsies. Speech and sensation are normal. His physical health is good, and examination reveals no disease of the abdominal or thoracic organs. The foreskin is very long, but there are no adhesions. There is no genital irritation, nor any bad habits.

Prof. de Schweinitz examined his eyes and reports: "R. E., V. = 15/xxx. Round disc, temporal edges clear; nasal and upper and lower margins hidden by grayish infiltration; much white tissue around central vessels. Veins full, arteries normal. L. E., V. = 15/xv (partly). Similar condition of disc, but blurring of disc less marked. Slight concomitant convergent squint. Eyes wander in under cover. Hypermetropia = 1.5 D. Slight astigmatism. Diagnosis: hemi-neuritis with hypermetropic astigmatism, and slight convergent squint."

The case was diagnosticated habit-chorea, treatment was given and the boy told to return in a week. Two weeks later he came back showing marked changes in the symptoms. Every few minutes the head is jerked violently and suddenly to the right or left. Previously the motions had been slow and gentle. An arm is very forcibly extended once, the legs are flexed and extended once. Similar movements elevate or depress the shoulders. These movements are independent of each other. That is to say, at any given moment any part may be involved, though oftentimes the legs move synchronously. The movements are shock-like, sudden, rapid and violent. They appear almost as if willed. During sleep they cease entirely. Emotional excitement increases them markedly. Voluntary motion of arm or leg decreases them for the time being in the member used, but has no effect upon the rest of the body. While lying down they are less severe than when up. There are no sensory failures. He was given Fowler's solution in increasing doses and ordered to be kept at rest.

After a few days the movements suddenly ceased, but were immediately followed by attacks of violent, barking, spasmodic cough, so severe as to alarm his parents. When next seen at the Infirmary he would every few minutes make a short, quick, explosive, grunting noise. When told to breathe deeply the cough stopped entirely. Expectant attention produced by having him fix his eyes upon a bright object had the same effect. Slight general choreiform movements were also present. Complete cure followed his admission to the Infirmary and subjection to the hospital discipline in bed for a few weeks.

REMARKS.—This case, as you see, looks like what I will call acute habit-chorea. The same power of control exists for a time as in Case I. The uneasiness under self-control is present. The abrupt cessation of other movements when the barking or grunting comes on is sometimes seen in habit-chorea, but in that disorder there are usually frequent repetitions, never violent, of the part disturbed. This lasts for days, and on ceasing is replaced by like movements elsewhere. These children may or may not be hysterical, but the hysteria of childhood often fails to give you a complete picture.

The grunting is not like the cough of hysterical women, and is probably only an incident of one of the forms of semi-spasmodic movement. At times it is due to sudden abdominal muscular contractions. Clinically and practically all this is interesting. Of this you may be sure, that when adults are afflicted with these forms of temporarily controllable semi-spasmodic motions, you will find them hard to get well. All the emotionalness of such temperaments as incline to motor disorder is increased by their presence. These people get self-watchful, depressed, and will-less. Children are easier to cure, no matter how grave the malady, or how distinct the hysteria. Always with them the changefulness of development assists, if you know how to use your opportunities. Isolate them, if possible. Insist on mild diet —as of milk or vegetables, or these combined. Keep them at rest, and by-and-by offer little bribes if they will allow you for definite and increasing periods to restrain the movements. The slight cases of habit-spasm may be enduring, and the more severe cases get well, like this good little fellow. There are cases which do not, and which develop into the disastrous states of mind and body I have delineated in my *Lectures on Nervous Diseases*. These failures are commonly due to the folly of parents. There is no worse enemy of a nervous child than a nervous mother. The peculiar violence and look of spontaneous action in the lad's spasmodic movements recalled to my mind a man who, many years ago, was my patient. He was subject—and for periods of a week or two—to a disorder of which, being a quiet bank-clerk, he was much ashamed. After a few days of general uneasiness, which made him restless and inclined to excessive exertion, he began to have spasmodic actions—like this boy's—a sense of profound unease for a few minutes, ended in a single motion of abrupt violence. A leg was thrown upward or back; an arm, with the fist clenched, struck out once with a look of purpose about the act which was contradicted by the fact that he had over and over hurt his hand by driving it against some obstacle. Once or twice he had hurt others. At times he would warn me or another of the coming risk. No cause for this peculiar state was ever found; nor do I know what became of the man.

Case of extreme multiple myoclonus of hysterical character in a male.—Some of you may recall the interesting case of last year, in a Hebrew in middle life who presented a striking illustration of multiple myoclonus. I reported it with others as curious spastic cases to the Neurological Association. I now recall it to state that the man has become well and walks about like others. I saw once, some years ago, a similar case, and they are very rare, and it too was hysterical and in a Hebrew.

And now I am able to read you the notes of another case of multiple myoclonus, clearly hysterical, and in a gentleman whom I saw lately in consultation in a distant State. As I have so lately discussed the possibility of these spasms originating in the cord, I shall not need to repeat my remarks.

Family history. C. B., aged thirty-five years, has no neurotic history or history of mental disease. Some of the remote ancestors were rather eccentric or peculiar in certain directions. His paternal uncle died, aged forty-five, of acute cerebral disease, said to have been encephalitis. One cousin, a son of this uncle, has had incoördination of all the extremities, choreic movements of the face accompanying voluntary movements only, and indistinctness of speech, which were first noted in infancy, but were not thought to have been congenital.

The mother's labor was normal, no instruments having been used. The child was somewhat backward in development; the anterior fontanel seems to have remained open unusually long. There was decided indistinctness and difficulty in speech, which only disappeared after some years. At school the boy was rather slow and seemed disinclined to learn. He was always a little peculiar; he had very strong opinions on various subjects which could not be readily influenced, and were different from those natural to his companions. For some years before his present attack (six years ago) he had been considered a little peculiar by neighbors. When about seven years old he was thrown out of a light wagon and the wheel passed over his head. No evidence of fracture of the skull was detected and he seemed well in a few days. When fifteen or sixteen years old, and while studying rather hard at school, he began to have severe frontal, bilateral headaches, which at first came after study only, but gradually persisted, although the study was given up, and after a time came in the mornings without apparent cause, lasting some hours, apparently often connected with the condition of the weather, being worse when there was a cold, piercing, or bracing wind. From this time the headaches have persisted, at first coming principally in the spring, while he was free from them through the rest of the year; later, occurring at any season, and gradually growing more frequent and more troublesome, so that, finally, he gave up his home in the city and lived entirely in the country. Study was found to be impossible. Change of climate made his sufferings worse. The patient led an out-of-door life, superintending and working on his farm until his present trouble commenced. He was an unusually large, strong, and muscularly well-developed man.

The present trouble began six years ago, some time after a moral shock, in which the emotions were much involved. He was attacked with unusually severe headaches, general lassitude, and inability to work, so that he left his farm for a time and came to live with his parents, who had a large estate in the neighborhood. While with them, he was one day, while driving, attacked, without apparent cause, with a fit of coughing, which lasted some minutes and was of a convulsive character, and so violent as to be alarming. After this, similar attacks of coughing came on almost daily, and seemed to be aggravated or provoked by driving. A few days later he began to have attacks of violent involuntary movements (clonic spasms), affecting the extremities; at first often unilateral, sometimes on one side and sometimes on the other. The lower extremities were more affected, on the whole, than the upper. The spasms, at first, occurred only on rising in the morning. After a few weeks, the attacks of coughing were largely replaced by attacks of hiccoughs, and it was found that the headaches, the cough, the hiccoughs, and the motor spasms were more or less interchangeable. Since this time, the general features of the affection have remained unaltered. The motor spasms have gradually become more frequent, for some years occurring daily at stated hours (periodic), with frequent intervening attacks, and

now occurring several times a day, and every day. The motor attacks consist of very violent, more or less regular movements of the extremities, especially the lower, when violent stamping or up-and-down movements follow each other with great rapidity; in the upper extremities there are regular coarse movements of the entire extremities. These attacks come on, especially at the regular times, without apparent cause, but are also produced at any time by a sudden, unexpected touch, or by any touch with which emotion is connected. They are also produced by motion (both sensori-motor and motor-motor spasms).

The paroxysms of cough disappeared after some months to a considerable extent, while the hiccoughs lasted only a few weeks, the place of both being apparently taken by the larger spasms of the limbs. During the last three years there have been many attacks of retching and vomiting (or regurgitation), without nausea, and, for the last two years, attacks of violent and forcible shouting; all of these are interchangeable with the others.

For a year past some loss of strength has been noticed and an increase in the ease with which the spasms are caused, especially by walking, so that they now largely preclude any attempt at exercise, as he states that he is liable to have his legs drawn from under him violently and suddenly, so that he falls to the ground. If walking be persisted in, in spite of the spasms, the headache becomes unbearable. Of late, the trunk has also been invaded by the spasms, the body being frequently bent to one side, usually the left; and clonic spasms in the trunk-muscles sometimes last for hours and even days (once apparently without remission for four days, but the patient was not seen while asleep), causing great soreness and tenderness in these muscles. There is now much dizziness, which began first six months ago, and now causes an additional difficulty in walking.

He has taken food irregularly for years; of late, not more than one meal of solids a day, and that usually at 11 P.M., and the rest of the time, weak coffee or milk, when wished for. The bowels are regular; the urine negative. The face is now pale, but becomes turgid and congested during attacks, partly from the violence of the motion, partly from or with the headache, which is likely to accompany them. The intellect is unimpaired (broadly speaking). Sleep has been good.

This gentleman, unlike our former case, is in easy circumstances. It were better he were not, as he is able to control his own surroundings and to isolate himself as he pleases. The limitations to which the position, age, and circumstances of the case subject our therapeutics must be clear to you. When I first examined this most expressively hysterical case I found my patient up, and after a partial examination, with increasing signs of fear and nervousness, he went to bed. There I completed a long, but, of necessity, imperfect study. He was a rather well-built, well-colored man, with no organic troubles. As I went on to make the ordinary search as to sensation, reflexes, etc., all being normal, he became all the time more and more convulsed. If I touched a leg, it passed at once into violent convulsion, and this at times involved all four limbs, and was so terrible that I thought the bed would be broken. When he tried to walk, and always then if emotionally disturbed, he would begin to stamp in a strange way and with swiftly increasing force, and this spastic state, reaching the trunk, seemed then to draw him down, so that he fell or contrived to get back to the bed. I was obliged at last to cut short my examination, but not before, with the aid of his physician, I was able to reach very distinct conclusions.

Cases of violent hysteria in the male are not common, at least in America. Only once in my life have I seen a male exhibit all the acts in the long drama of hysteria precisely as we so often see them in the female. I now add the opinion given in the case of Mr. C. B. A careful consideration of the symptoms brings me to three conclusions:

(1) That the form of the convulsive attacks brings this disorder closer to the clinical delineations of myoclonus than to those of any other group of symptoms.

He is liable to have violent stamping, or worse, from standing, *i. e.*, sole-pressure causes it. Also, when cognizant of it, a mere touch anywhere brings on clonic spasms of the legs if these be touched, or of the arms under like circumstances. Voluntary motion may, as in other cases, give rise to like spasms, *i. e.*, the spasms as to cause may be sensori-motor or moto-motor.

(2) Evidently attention increases the severity of sensori-motor manifestations.

(3) For various reasons, this myoclonus seems to me hysterical. The transfers, the interchangeableness of spasms, headache, regurgitation, hiccough, and vocal symptoms, all point this way. So do the type of laryngeal phenomena, and the characteristic regurgitation without nausea; and that the first spasms followed a grave emotional disturbance, assists us to a like conclusion. The original injury may have been contributive, but there is not in the skull any very distinct local evidence of organic lesion.

If it all be at last hysteria, or, due to the injury but in its outcome hysteric, one might look to find sensory changes; but close examination of the skin is impossible, and without ether I could not see the eye-grounds, as I wished to do. It would be worth while once to do this under ether. Probably the spasms have their birth in the cord. They seem to me in quality and history functional, and I ought to add that, when off guard—a rare thing—the touch of my hand does not occasion spasm, nor does his own touch of himself, unless, one having asked if it be so capable, he with pre-attention touches himself.

Probably he is incurable, but this does not imply the certainty of his not losing the spasms—as may come about. If he were a lad, I would take him away, and with isolation, massage, and electricity treat him, and have hope. Now, I do not advise it. I should like to see hypnotism used. I would assuredly use for a year arsenic. I would not let him live wholly alone or unvisited by friends, as he would wish to be the case.

Hypodermatic use of arsenic is to be considered.

I have little doubt that the injury may have been the ultimate cause of headache, and that he has had more or less of chronic meningitis. If he could have a good study of the eyes by an expert, I should feel better satisfied, as the eyes may, with slight ocular defects, be competent to trouble a defective brain. Also, the color-fields might prove very interesting.

I gather enough in various ways to make me think

that Mr. C. B. was never a perfectly normal person in earlier youth. When, to a person of such neurotic type, come accident, emotions, etc., then the worst and the more unusual results are to be apprehended.

Yet a word before I close the lesson of the day. I have used the label hysteria again and again. It is, and as yet must be, a word of somewhat loose employment. I am not sure that it is just to apply it, because with spastic or other symptoms the patient is merely emotional, but certainly we, by common consent, do this, especially in the unusual forms of spasm and in cases in which clearly emotion, as in Case I of to-day, was the parent of the spasms, and by its added increase proportionally developed the number or violence of the movements in question. When we have areas of anesthesia we use the term in question with lessened doubt. If, too, without organic change we find these, and with them optical anesthesia for colors or especially reversals of the color fields, our doubts are further lessened. But after all it is the grouped conditions which fully justify such clinical labels. Dr. J. K. Mitchell and Prof. de Schweinitz have shown how much our American experience as to the eye-symptoms of hysteria may vary from those of the French observers.

A greater surprise in this direction was given us lately by the case of a double fracture of the spine in a most wholesome-minded girl, free from the least trace of hysteria. In her, to our amazement, there was complete reversal of the color fields. The case will be more fully related elsewhere.

ORIGINAL LECTURE.

TRAUMATIC MYELITIS.

A Clinical Lecture[1]
delivered at the Arapahoe County Hospital, October 1, 1892.

BY J. T. ESKRIDGE, M.D.,
PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; NEUROLOGIST TO THE ARAPAHOE COUNTY, TO THE ST. LUKE'S AND TO THE DEACONESS HOME HOSPITALS.

GENTLEMEN: I wish to call your attention to-day to a case of traumatic myelitis. The history is as follows: G. S., nineteen years of age, of New York, a widow, by occupation a housemaid, came to Colorado in 1890. The family history is unimportant. She seems to have enjoyed excellent health until the 23d day of August, 1892, when she was shot in the back on a level with the ninth dorsal vertebra. She immediately fell, unable to move her legs. She was admitted to the hospital two days later, and at the examination, August 25th, her condition was noted as follows: Her mind is clear and she is entirely free from pain. The leg muscles are completely flaccid, and foot-drop exists to an extreme degree, but the foot can be passively brought to a right angle with the leg, and can be dorsally flexed without any resistance. There is a slight plantar reflex, and this is equal on both sides. Ankle-clonus is absent, also the knee-jerks, both direct and reinforced. Paralysis of the sphincters of the bowel and bladder is complete. All the superficial reflexes, with the exception of the plantar, up to the eighth rib, are completely abolished. Tactile sense is completely lost from the eighth intercostal space downward on both sides of the body. Pain, pressure, muscular, localization, temperature, and posture senses are abolished over the anesthetic area. Normal sensation begins at the eighth intercostal space, without any area of hyperesthesia, and is normal from this space upward. There is no disturbonce of the heart's action or respiratory functions. The external bullet-wound is small, and is three-quarters of an inch to the left of the spine, opposite the ninth dorsal vertebra.

When the woman was brought into the hospital, two questions suggested themselves in regard to the treatment: Should we treat the case simply as one of traumatic myelitis, or should we recommend a surgical operation? Under the modern system of aseptic and antiseptic surgical procedures, an operation, *per se*, either on the brain or the cord, is not attended with much danger. The probability here of pressure on the cord, either by hemorrhage into the spinal canal, or by a spicule of bone which had been carried by the ball, or by the presence of the ball itself, made it almost obligatory to recommend a surgical operation, because so complete abolition of all functions of the cord suggests that we might have had some direct violence to the cord at the time of the shooting. The strongest reason for not operating was this same complete abolition of the functions of the cord below the level of the eighth intercostal space. It is now pretty generally conceded by neurologists that when the knee-jerks remain permanently abolished after an injury to the cord in the dorsal or cervical region, the cord has been completely destroyed at the point of lesion. Ordinarily under such circumstances, an operation for the relief of pressure on the cord (even if the cause of the pressure were found and removed) could be attended with no good results; because, in no instance, so far as we know, after complete division of the human spinal cord has occurred, has union of the divided ends of the cord taken place.

In dealing with such a case as the one under consideration, it must be borne in mind, however, that after all severe injuries to the cord, either in the cervical or dorsal region, even when complete continuity of the cord has not been destroyed, the reflexes, both deep and superficial, are abolished, and remain so for several hours or days, depending upon the severity of the shock to the central nervous system. In cases of incomplete division, when the reflexes return, the superficial reflexes reappear before the deep and become exaggerated in advance of them. At the time we were called upon to determine the advisability of an operation, only thirty-six hours had elapsed since the reception of the bullet-wound, and although the knee-jerks were still absent, there was a feeble plantar reflex in each foot. The position taken by the surgeon on duty, Dr. Boice, and the others of the surgical staff of the hospital, Drs. Rogers and Parkhill, as well as by myself, was that the case was too grave to permit of any delay, if an operation were to be performed at all; and as the plantar reflexes, though feeble, were present, we might have sufficient pressure on the cord to abolish its function almost completely for the time being, even if entire solution of continuity had not taken place.

An immediate operation, consisting of exposing the

[1] Stenographically reported by Miss Lottie M. Page.

spinal canal by removal of several laminæ of the vertebræ, was decided upon.

The next question to decide was the seat of the operation. The ball had pierced the skin opposite the body of the ninth dorsal vertebra, and, on probing, the direction of the bullet-wound seemed to be upward and slightly outward, so that from the position of the external wound we had no definite localizing symptoms of the exact seat of the lesion in the cord. For localizing purposes, however, we had two important symptoms: the upper limit of the area of anesthesia and the condition of the superficial reflexes. The cutaneous surface over which are found the abdominal reflexes (the lower elicited by smartly stroking the skin of the abdomen by means of a lead-pencil, the blunt points of the esthesiometer, or some such agent, just above Poupart's ligament on either side; and the upper, found in like manner in the epigastric region) is innervated by the spinal nerves that come from the cord between the sixth and eleventh dorsal segments. In the patient whose case is under consideration, the lower abdominal reflexes were absent, and the epigastric could be found only in the extreme upper epigastric region near the ensiform cartilage. From this condition of the superficial reflexes it seems to me that we were justified in locating the cord-lesion somewhere between the ninth and sixth dorsal segments. I have directed your attention particularly to the superficial reflexes in this case, not so much for their localizing value in such a case as this, in which the myelitic lesion is severe, and the upper limit of the area of anesthesia is definite and well outlined, as to call your attention to their value in slighter cord-lesions, in which you may have no sharp upper limit of the area of anesthesia. In the case of the patient before us, it was the upper and sharply-defined limit of the area of anesthesia by which the lesion in the cord was localized.

In the dorsal region the cutaneous nervous supply of the intercostal spaces corresponds in number with the number of the segment of the cord from which the nerve is given off, so that as we found complete abolition of all sensory phenomena in the ninth intercostal space, and a more or less complete preservation of the same in the eighth intercostal space, we could with some certainty locate the lesion in the ninth dorsal segment of the cord. As a general statement it may be said, that the dorsal spines are opposite segments of the cord number two or three below the number corresponding to a given spine. For example, the eighth dorsal spine is opposite the tenth, or a point between the tenth and eleventh, dorsal segments of the cord.

In the patient before us it was decided to expose the spinal canal by removal of the laminæ of the fifth, sixth, seventh, and eighth dorsal vertebræ, without separating the spines from their ligamentous attachments, thus following the operation devised and executed by Dr. Abbe, of New York. The operation was performed by Dr. Boice, assisted by Drs. Rogers and Parkhill.

On exposing the spinal canal the dura seemed to be normal in appearance, and pulsation in the cord was felt and seen. No cause of pressure, either from the presence of the ball, depressed bone, or effused blood, in the spinal canal, external to the dura, was found. The laminæ of the fourth dorsal vertebra were removed, and still no cause to account for the cord-lesion was apparent. As the dura was uninjured and the membranes of the cord did not contain an undue quantity of fluid, it was thought best not to expose the cord. At the operation neither the ball nor its tract was discovered.

The wound was dressed in the usual manner, and the patient placed in bed surrounded by moderately warm bottles, not sufficiently hot, however, to cause eschars over the anesthetic area. The wound healed without the formation of pus. The temperature rose considerably at first, but there was no great constitutional disturbance. The temperature on admission was 101.5°. The day after the operation it rose to 103.5°, but that night it dropped to 102°. The next day it rose to 103° and then dropped to 102°. This was on the third day after the operation. On the fourth day it dropped to 99°. Since then the temperature has been more or less vacillating, usually remaining about 1.5° above normal. On the 7th of September it rose to 104.4°, but at no other period has the temperature gone beyond 102.5°. The pulse and respiration have been good until recently. The patient's condition has not been made worse by the operation, although there have been no directly good results from it. The patient has eaten fairly well, but has been restless, and there have been evidences during the last three weeks that the myelitis has been ascending. On examination to-day the plantar reflex of each foot is found quite distinct, and a decided jerk of the muscles of the legs takes place when these reflexes are elicited. Occasionally a decided twitching of the muscles of the legs occurs spontaneously, but in the left leg to a less degree than in the right. The woman speaks also of feeling a tingling sensation in the legs from the knees down. The latter has been constant almost since the operation, while the twitching has only existed for about two weeks. I desire to call your attention to the flaccid condition of the muscles of the legs. The feet are plantar-flexed by their own weight until the insteps are on a line with the tibia. The muscles are considerably wasted. The left leg is considerably swollen, and the left foot to an enormous degree. The right foot and leg are only moderately swollen. We have complete paralysis of all muscles, including the sphincters of the bladder and bowel, up to the fifth or sixth intercostal space. With the exception of a slight plantar reflex, all the reflexes, both deep and superficial, are abolished from the sixth intercostal space downward. The epigastric reflex is now absent, although it was present immediately after the shooting. All sensory phenomena are abolished from the sixth intercostal space downward.

The trophic disturbances in our patient have become well marked. The most serious is the formation of a sacral bedsore, which extends over a considerable area, and has laid bare the muscles. Slough after slough has formed, and in spite of the best attention and most careful nursing the sore is constantly increasing in size and malignancy. Small sores have formed on the posterior surfaces of the heels; in fact, wherever pressure is exerted, as over the calves of the legs, the posterior surfaces of the thighs, and over each hip, it is only with great difficulty that sores have been prevented. Careful attention has been given to the bladder, but notwithstanding the vigilance

of the resident physician, Dr. Mavity, and of the nurse, a cystitis has resulted. So far, the kidneys do not seem to be affected. The swelling of the feet and legs is another evidence of the marked trophic disturbance. It is probable that some effusion has taken place into the ankle-joint and knee-joints.

[The patient was now removed from the clinic room.]

We will now consider the probable nature of the spinal-cord lesion from which our patient is suffering. You remember that at the operation, performed August 25, 1892, the spinal canal was exposed from the fourth to the eighth dorsal vertebra inclusive, by the removal of the laminæ, but that no direct injury to the cord was found from the presence of the bullet, or from spiculæ of bone, although the paralysis was sudden and complete, from the eighth dorsal segment of the cord downward, from the moment the fatal shot was fired.

In the absence of direct injury to the cord, the lesion must have been a vascular one, a result of a violent shock to the spine, probably caused by the ball striking against the body of one of the vertebræ. It must have been either a hemorrhage in the substance of the cord or in the membranes, or, both a cord and meningeal hemorrhage might have occurred at the same time.

In cases of spinal meningeal hemorrhage, the paralysis, sensory and motor, is never complete, and there is great pain in the back and down the limbs, with spasmodic contraction of those muscles supplied by the spinal nerves irritated by the presence of the effused blood. Our patient has suffered but little pain in the back, none in the limbs; there has been no muscular spasm, and paralysis was complete from the moment of the injury. We can, then, exclude simple spinal meningeal hemorrhage.

Was there a double lesion—a cord and a meningeal one? If a meningeal hemorrhage in such a case as this were to occur only below the point of the cord-lesion, no symptoms would be produced by it; but we can scarcely conceive of such a state of affairs, for the meningeal hemorrhage would probably be greatest at the point where the violence of the shock expended itself upon the cord and membranes. Under such circumstances the meningeal hemorrhage would extend upward and downward, both above and below the cord-lesion, and the hemorrhage in the membranes above the cord-lesion would give rise to the usual symptoms found to attend a simple spinal meningeal hemorrhage unattended by any direct cord-lesion. Further, we found at the operation, thirty-six hours after the shooting, no evidence of effused blood in the membranes.

It seems to me we are justified in concluding that at the time of the reception of the shock a hemorrhage occurred in the gray substance of the cord, sufficiently large to destroy completely the function, if not the substance, of the cord at the seat of the hemorrhage.

About two years ago a man was admitted into one of the nervous wards of this hospital, completely paralyzed, both for motion and all forms of sensation, from the first dorsal segment of the cord downward. He had been sitting on a fence, about four feet in height, when suddenly he lost his balance and fell backward, striking the ground with his spine in the cervico-dorsal region. Paralysis was immediate and complete. He died about one week later of ascending myelitis. At the autopsy the bones were found in a normal condition, but at the first dorsal segment the cord was semi-fluid and pulpy, and when the cord was cut at this point its substance ran out like pus, as when an abscess is opened. The broken-down cord-substance was discolored with partially coagulated blood. Effused blood was found in the central portion of the cord, just above and below the pulpy portion. About three years ago I saw, in consultation with Dr. Pfeiffer, in the Union Pacific Hospital, a case almost identical with the one just related. In both of these cases there was complete abolition of all the reflexes, deep and superficial, below the point of the cord-lesion. It is probable that at the autopsy of the patient whose case we have studied to-day (for death is sure to take place in a comparatively short time), we shall find the cord softened and pulpy at about the ninth dorsal segment, with a pus-like substance stained with blood, should death not be postponed until the coloring matter of the blood all disappears.

Cases like the one we have been studying to-day are properly termed hematomyelia. When the hemorrhage in the cord is large, it is almost always due to traumatism of some kind, and usually to direct violence to the spine.

The symptoms are those of acute and destructive myelitis, with these exceptions: they come on suddenly, and are unattended with any initial rise of temperature, but, on the contrary, the temperature is, as a rule, subnormal until the patient begins to react from the shock.

The symptoms of acute myelitis are motor, sensory, reflex, and trophic in character. They vary in intensity in proportion to the mildness or severity of the inflammation, and are modified by the segments of the cord involved in transverse myelitis, the most common form of the disease.

The symptoms of myelitis in a severe and destructive form have been too well demonstrated by the case which we have studied to-day to require any repetition of them.

I wish to call attention, at present, to the condition of the reflexes in myelitis. In all severe forms of myelitis that come on suddenly, and in all cases of hemorrhagic or central myelitis, there is an initial period of inhibitory abolition of all the reflexes below the seat of the cord-lesion. If the lesion has occurred in the lumbar region of the cord the reflexes in the legs remain absent until well on into convalescence, and the knee-jerks may never become normal, although recovery be almost complete. Even in the lighter forms of acute myelitis in the lumbar region of the cord, the reflexes (especially the knee-jerks) in the legs remain absent throughout the course of the disease. When the disease affects the cervical or dorsal portion of the cord, after a few hours, or a day or two, subsequently to the invasion of the cord by the disease, the reflexes in the parts below the lesion return and are considerably exaggerated. In central myelitis the reflexes are early, and permanently, abolished.

It is probable that in all injuries to the cord that completely sever the continuity of the cord at the seat of lesion, no matter whether it occur in the cervical or dorsal region, all reflexes below the point of severed continuity are immediately abolished, and remain so until the death of the patient. From the teachings of experimental physiology, we were formerly led to believe

that a complete solution of the continuity of the cord in the cervical or dorsal region was followed by an increase of the reflexes below. This is probably correct in some of the lower animals, but pathologic observations on man seem to prove that this is not the case with him.

Some two or three years ago, Bastian, of London, brought forward several cases in which the cord had been completely severed, either in the cervical or dorsal region, and in all of them the reflexes below the lesion were completely abolished. Since the report of Bastian's cases, several similar ones have been put on record by American and European writers. So far, I have observed four cases in which the cord was completely destroyed at a point above the lumbar enlargement, and in each one of them the reflexes below the cord-lesion remained permanently absent.

These observations are of more importance than we, at first thought, might be inclined to think. In cases of injury of the cervical or dorsal region of the spine in which all cord-functions, including the reflexes, both deep and superficial, remain absent several days, or for periods of indefinite lengths of time beyond this, no operation for the relief of pressure on the cord is justifiable. I wish to remind you again that slight lesions in the lumbar region of the cord may permanently abolish the reflexes, especially the knee-jerks, and that in lesions of the cervical or dorsal region there is usually an initial inhibitory abolition of the reflexes.

Whether the case of the patient who has been before us to-day is one of complete or partial destruction of the cord at the seat of lesion remains to be determined. I think we shall find at the autopsy that some of the fibers of the cord remain intact. You remember that all the reflexes below the eighth intercostal space, except the plantar reaction, are absent, yet the presence of this reflex, with the feelings that she experiences of drawing of the feet, and a tingling sensation in the parts below the knees, point to the existence of some undivided fibers of the cord.

What is the prognosis, both as to the immediate danger to the patient's life, and as to the permanent results of the disease, in cases of more or less complete destruction of cord-tissue at the seat of injury?

The seat of the lesion, whether it is in the cervical, dorsal, or lumbar region of the cord, has much to do with the immediate prognosis. When it occurs in the cervical region the prognosis is worst, because of the interference with respiration and the heart's action. When it occurs in the lumbar region the prognosis is worse than when it takes place in the dorsal, because of the great trophic disturbance, especially the formation of a large sacral bedsore. The immediate prognosis in lesions of the dorsal region is good, provided ascending myelitis does not take place. In our patient the inflammation has been gradually ascending for nearly two weeks, until now most of the intercostal muscles are paralyzed, and she suffers from severe attacks of dyspnea. The lungs are filled with mucous râles, so that life will not be prolonged beyond a few days or a week or two, unless the inflammatory process should cease to ascend, which is very improbable.

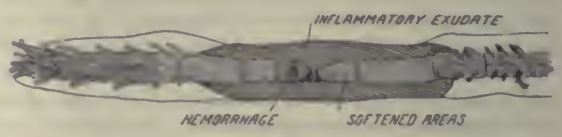
The permanent prognosis in all such cases as the one we have studied to-day is bad, even should ascending or descending myelitis not result. The cord recovers, at best, very imperfectly from lesions that destroy the integrity of its structure. In all severe destructive lesions, even in the dorsal region of the cord, life, at best, is but a lingering death, and the patient is made miserable and helpless from chronic ascending and descending degenerations.

The treatment of the patient has consisted in trying to make her as comfortable as possible; in endeavoring to lessen the inflammatory process; in paying especial attention to the bladder; and, at first, in trying to prevent the formation of bedsores, and, later, in treating the sores whose formation we were unable to prevent.

Subsequent history of the patient, with autopsy. The history of the patient after the lecture is briefly told. Life was prolonged much beyond the time anticipated on October 1st. The progress of the disease was slow, but steady. The plantar reflexes were not obtainable after the 2d of October, and no sensations were experienced in the legs after the 5th of October, seventeen days before death, which occurred October 22d.

At the autopsy, twelve hours after death, neither the abdominal, thoracic, nor cranial cavity was opened.

The body was greatly emaciated, and there was great edema of the legs and feet. The sacral bedsore was about six inches in diameter, and in its center nearly all the soft tissue had sloughed off, and the bone was exposed. Several small pressure-sores were found on the posterior portions of the legs, and on the buttocks and hips. On exposing the spinal canal, from the upper cervical region to the sacral, the external surface of the dura seemed to be in a normal condition, except that a few adhesions were found in the region of the operation. On opening the dura a thick layer of yellow pus was found surrounding the pia and cord from the fourth to the eighth dorsal vertebræ, throughout the extent to which the canal was exposed at the surgical operation which was performed



August 25th, nearly two months before. On placing the cord in water all the pus readily separated from the cord and membranes. The cord at the ninth dorsal segment was a soft pulpy mass, and on cutting it across at this point the softened cord-substance ran out, looking like pus, and showing the cord to be almost completely destroyed for a space of nearly half an inch in length. Some fibers of the anterior portion of the cord at the seat of the greatest softening had not broken down, but they were swollen and greatly softened. Immediately below the point where the cord-substance had been almost completely destroyed, a few blood-stained spots were found in the gray substance of the cord, but none were found above the destroyed area. On section of the cord into short segments, both above and below the ninth segment, the cut edges became everted, and the cord appeared swollen and softened up to the second or third segment above, and down to the lumbar enlargement below. The cord was preserved for microscopic examination. The macroscopic appearances of the cord and membranes are shown in the annexed illustration.

CLINICAL MEMORANDA.

AN OPERATION FOR RE-COVERING THE DENUDED CRANIUM.

BY HALDOR SNEVE, M.D.,
OF MINNEAPOLIS, MINN.;
LATE A. A. SURGEON NATIONAL MILITARY HOME, DAYTON, OHIO;
LATE ASSISTANT SUPERINTENDENT OF THE DAYTON ASYLUM FOR THE INSANE.

IN the early period of American frontier life, toward the close of the eighteenth century, an operation was practised, that for originality of design and boldness in execution has rarely been equalled in the annals of surgical science.

The operation consisted in making multiple perforations through the denuded external table of the skull down to the diploë, to invite granulation-tissue to appear in the openings thus made, in order to fill up the denuded spaces, and thereby protect the bare skull and prevent exfoliation of the bone, with consequent exposure of the brain.

In an address delivered at Nashville, Tenn., in April, 1855, and afterward published in the *Nashville Journal of Medicine and Surgery*, Dr. Felix Robertson describes the case of one Thomas Hood, who, in the year 1781, was scalped and left supposably dead by the Indians, but was afterward treated, by Dr. Robertson's father, in the manner described, the patient living many years afterward. He said:

"Dr. Robertson, Sr., had seen many persons who had been scalped in East Tennessee, and had there learned from a travelling French surgeon how to treat them. This was to perforate the outer table of the skull with a shoemaker's awl over the whole naked surface, making the perforations close together. Through these perforations, granulations sprang up, and, gradually spreading, finally united and formed a covering to the denuded skull before it should die and exfoliate, and thus expose the brain. I am sorry I cannot recollect the name of the French surgeon who introduced the practice, for he deserves to have his name immortalized for the great boon he bestowed on the frontier settlers of that day. This operation became in time so common that there were persons in every fort who performed it."

To an unknown French surgeon, therefore, belongs the credit of having conceived this most unique procedure. It would be interesting to know whether science or accident were responsible for the conception. A knowledge of the anatomy of the parts, and the physiologic laws governing the reproduction of tissues, could have suggested to him the operation; and, on the other hand, clinical observation of granulations springing from an exposed diploë might have done so. The knowledge of this procedure seems to have been lost after a time, as there are no records that I can find of its having been resorted to on the frontier during the last forty or fifty years, although numerous instances have occurred of individuals who have been thus mutilated by the Indians and recovered with bare crania.

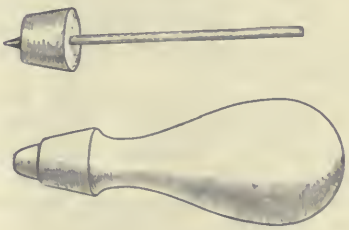
The late lamented D. Hayes Agnew, of Philadelphia, refers, in his *Text-book of Surgery*, to the case of a young lad in whom part of the parietal bones was exposed from a severe injury to the head, in which he adopted the procedure. He says: "Little red points made their appearance through the openings, but their ultimate destiny and their influence on the table were rendered negative by the sudden death of the patient from convulsions."

On October 11, 1888, T. J. W., forty-eight years of age, in fair state of physical health, was admitted to the Dayton (Ohio) Hospital for the Insane, suffering from dementia, and presenting a denuded space over the left parietal bone, of an oblong shape, about two and a half inches long, and two inches wide, caused by falling on a hot stove. The skull at this point was destitute of periosteum, and apparently healthy. The margins of the scalp were raw and unhealthy in appearance and constantly secreted an acrid, offensive fluid. During the following winter many efforts were made by the physician in whose ward he was to bring the margins of the scalp together, but without permanent success. In April, 1889, assisted by Dr. R. F. Gundry, I perforated the external table, making thirteen perforations at equal distances apart, one-eighth of an inch deep. The depth was determined by the feeling of lessened resistance to the instrument.

FIG. 1.

A small drill was procured, one-sixteenth of an inch in diameter, and a wooden cork placed over the end, leaving one-eighth of an inch of the drill-point projecting; the other end was fastened in an ordinary awl-handle. The denuded surface and instrument were then

FIG. 2.



rendered aseptic, and the drilling, which seemed to cause no pain whatever, proceeded with. A very small amount of blood-stained serum moistened the apertures. An antiseptic dressing was next applied and the patient dismissed. On the twentieth day, small red points were visible in the openings thus made, which grew rapidly,

spreading out until the entire bare surface was covered by healthy-looking granulations; these grew upward to the level of the surrounding scalp, and became covered in time by an unhealthy-looking cuticle, which ulcerated in spots repeatedly; to remedy this, small skin-grafts taken from the shoulder, after Reverdin's method, were applied, and the whole cicatrized nicely.

Two years after, the scalp at this point presented one or two small spots which alternately ulcerated and healed repeatedly; but, on the whole, the operation was a success, and the appearance was vastly superior to that of the denuded white bone.

The granulation-tissue was probably of low vitality, as is so often seen in the cicatrization of old tibial ulcers when extending down to or into the bone, and this is probably the reason of the imperfect skin-formation.

A short *résumé* of the anatomy of the parts under consideration may aid us in more clearly understanding how it is possible for granulation-tissue to sprout up through apertures in the outer table of the skull, and why it is so difficult to cover denuded surfaces on the skull with the scalp if any considerable loss of substance obtains. The diploë is a vascular tissue of varying thickness, situated between the two compact tables of the skull, and consists of bloodvessels, a small amount of areolar tissue, and medullary cells. (Kölliker.) The veins of the diploë are very numerous, and particularly large and tortuous; the canals containing them having sides formed of thin lamellæ of bone.

The coats of the veins are formed only of epithelium and rest on a layer of non-elastic tissue, so that when the bone is divided they remain patulous and do not contract in the canal in which they are contained. As age advances, the diploë is absorbed and compact tissue takes its place. The outer table varies a great deal in thickness; the locality, age, and race having much to do in its determination.

The scalp can surgically be considered as one structure, as the skin, areolar tissue, fascia, and aponeurosis of the occipito-frontalis are so intimately joined together and move in unison. Sutures that are subjected to any tension in wounds through the aponeurosis will usually tear out, because of the non-elastic structure of the scalp.

The knife of the Indian is now devoted to more peaceful pursuits than scalping, but machinery and traumata of various kinds perform this function frequently, and one of the objects of this essay is to call the attention of the profession to this almost forgotten resource in those cases in which ordinary means fail to restore the coverings of a denuded cranium.

There are two dangers connected with the operation:

1st. *Septic absorption*, with its sequelæ; rendered easy by the structure of the veins (non-contractile).

2d. *Perforation* of the *inner* table in very thin skulls.

Modern antiseptic surgery supplies the remedy for the first, and *care* will guard against the latter.

The Ophthalmological Section of the Pan-American Medical Congress has been organized with Dr. Julian J. Chisolm, of Baltimore, as Executive President, and Dr. J. Harris Pierpont, of Pensacola, as Spanish-speaking Secretary, and Dr. Geo. M. Gould, of Philadelphia, as English-speaking Secretary.

REPORT OF A CASE OF DERMATITIS MEDICAMENTOSA FROM IODOFORM, POTASSIUM IODID, AND ARISTOL.[1]

BY GEORGE G. HOLSTEN, M.D.,
DERMATOLOGIST TO THE BROOKLYN E. D. HOSPITAL DISPENSARY; PHYSICIAN TO THE BROOKLYN THROAT HOSPITAL, DEPARTMENT OF DERMATOLOGY.

ABOUT the 11th of October, the patient, a male, aged thirty-two, had been treated by some physician for an abrasion of the skin over the left elbow with iodoform and gauze dressing, and was told to return the following day to have the dressing renewed. Instead of doing so he permitted the dressing to remain on for several days, when, on account of the pain and swelling, he consulted a second physician, who gave him medicine and an ointment. The arm becoming worse, and an eruption having appeared on his hands, wrists, and various other portions of his body, he came to the skin clinic of the E. D. Hospital on October 25th.

The second physician had given him two medicines and an ointment. These were examined some time afterward. One medicine resembled Fowler's solution, but did not respond to tests for arsenic; the second was an aqueous solution of potassium iodid, presumably a saturated solution. Of this latter he had taken, beginning on the third day before I saw him, five drops every three hours, and had taken altogether about eighty drops. The ointment was apparently zinc ointment.

The left arm, from the shoulder to the finger-tips, was very much swollen. Covering the elbow were the remains of an immense bulla, fully ten inches in length, and almost encircling the arm. The peripheral portion was still filled with thin pus, while the central portion having broken down exposed a raw, oozing surface, with abundant exudation of serum and pus.

Over the left side of the thorax was a broad patch of erythema, made up of minute dots surrounding the follicular openings. In the center of the patch the edges of these dots touched each other, presenting an apparently homogenous appearance, while along the periphery the follicular redness became isolated.

The extensor surfaces of both hands and wrists presented a peculiar eruption. Both hands were swollen, bluish, and cyanotic, and scattered over them and the wrists were bluish-red macules of about one-quarter inch diameter, which toward their centers became raised and infiltrated, and minute papules, or vesicles, were seated on top of these slightly raised macules, or, more properly, maculo-papules. The center of each maculo-papule corresponded to a lanugo hair, which could be seen sticking through it. The palms were free. Over the notch of the sternum was a small patch of eruption similar to that on the hands. The first eruption (on the hands) had appeared five or six days previously.

The man was thin, poorly nourished, with universal glandular enlargement.

The suppurating surface was thoroughly irrigated with a saturated solution of boric acid, and dressed with an ointment containing 7 per cent. of ichthyol and 12 per cent. of boric acid.

By October 27th the eruptions on the hands and

[1] Read at the eighty-seventh meeting of the New York State Medical Society, February 9, 1893.

wrists were fading, and showed well their follicular site; the mouths of the follicles were more prominent than normally. Some of the papules on the chest-patch had become pustules. A few purplish-red papules had appeared on the legs. By the 29th the eruption on the hands had faded very much, only consisting of spots of a tawny-yellow to a brown color. A second eruption of bright-red papules had appeared scattered in the midst of the older fading eruption, yet likewise localized around the follicular openings, while here and there small, flaccid, sero-purulent bullæ had appeared on the hands. At the same time a bright-red, slightly raised, papular eruption had appeared over the entire chest. The ulcerated plaque on the elbow had healed, excepting a small area in the center; on this aristol was dusted. The following day this plaque had become very red, the ulcerated area was larger, and the patient complained of pain and heat. The aristol was thereupon discontinued. By November 5th all the eruptions had faded, so that but little remained of them. The abrasion over the elbow was entirely healed.

One of the striking features of this case is that the local application (and presumably the absorption) of an iodin compound gave rise to an eruption, not only around the site of local application, but also at quite a distance from it—on the chest and the opposite hand, with a considerable interval of sound skin. Another feature is the occurrence of the same phenomena a week later from the internal administration of a small quantity of another iodin compound, and the local reaction produced by still a third iodin compound; these three series of phenomena being a purely local effect from the aristol, a local and constitutional effect from the iodoform, and a constitutional effect only from the potassium iodid.

The local effect of iodoform on certain persons is that of an irritant, most probably due to the contained iodin. It is in all respects similar to the effects of any irritant on the skin, producing, according to the quantity employed, length of time of application, purity of the drug, and susceptibility of the skin, all grades of inflammatory reaction, from simple hyperemia to severe lesions of the skin, and confined to the site of application and the immediate surroundings.

When introduced into the system, however, whether by absorption through the skin, mucous membrane, or from some cavity, the eruption which may follow may appear on any portion of the body, either universally, or, as in this case, only in certain places. The eruption varies in intensity; it is most frequently erythematous, or eczematous, although quite severe lesions are sometimes produced.

Constitutional disturbances, which are generally of more frequent occurrence than are cutaneous manifestations, may or may not be present at the same time. These are at first slight anorexia, headache, depression or excitation, sleeplessness, slight delirium, but they may go on to violent headache, delirium, insomnia, and great prostration, with fever and emaciation, coma, and collapse. It has been observed that constitutional effects occur oftener after the prolonged use of iodoform, while exanthems appear earlier; further, that the more quickly the rash appears the more general is it likely to be.

The rapidity of an outbreak after the ingestion of an iodin compound differs very much. In some cases the eruption appears in a very short time—a few hours—after the first dose, while in others it may not appear until several weeks have elapsed. In this case there seemed to be an interval of from five to six days after the first application of iodoform was made, and the same period of time elapsed after the first dose of potassium iodid was taken.

The reaction of this patient to these three different iodin compounds showed a peculiar susceptibility to iodin in any form. It has frequently been observed that certain persons may have a susceptibility to iodin in one form, but have little or none to other forms of this element.

The reaction to the local application of aristol was so prompt and severe, causing pain and inflammatory symptoms and destroying newly-formed epidermis, that it is quite probable constitutional effects would have appeared had its use been persisted in.

This case was also of interest from the close resemblance the eruption bore to certain syphilitic eruptions, and it is this fact which probably led to the administration of the potassium iodid.

The first eruption on the hands resembled in color very much a papulo-tubercular syphilide, but was distinguished by the rapid development, absence of grouping, presence of erythema between the papules, and absence of the firm fleshy feel which the papulo-tubercular syphilides have.

The patches on the front and side of the chest, as well as the second eruption on the hands, had too rapid a development and were too localized to be an early papular syphilide. Further, the presence of hyperemia, itching, and burning, and the absence of the hard, almost shotty feel of a papular syphilide were points in differentiation.

340 Lafayette Avenue.

EXCISION OF THE GLADIOLUS FOR SARCOMA STERNI.

By SCHUYLER C. GRAVES, M.D.,
VISITING SURGEON TO THE U. S. A. HOSPITAL, AND SURGEON TO THE CHILDREN'S HOME, GRAND RAPIDS, MICH.

Mrs. D. D., aged forty-four years, came to me two years ago for carcinoma mammæ of the right side, situated in the upper and outer quadrant. The entire breast was removed, and the neighboring axillary space cleared of lymphatics, on January 18, 1891.

The case recovered promptly, and all went well until the latter part of September, 1892, when the patient discovered a small, painful nodule, the size of a large hazelnut, at the right edge of the sternum, attached to the costal cartilage of the third rib. The little tumor was watched carefully for a few weeks, and it grew quite rapidly. It was firmly fixed to the cartilaginous and osseous structures beneath. Immediate excision was suggested, but the patient did not consent until November 23, 1892, at which time the operation was done. My hospital notes afford the following summary of the case:

"About two months ago a nodule appeared near the right edge of the sternum, hard, painful, and attached to the underlying bone and cartilage. Malignancy was

suspected. The nodule grew rapidly, involving the costal cartilages of the second, third, fourth, and fifth ribs, and the corresponding edge of the sternum. On the foregoing date it was cut down upon and all the diseased tissue excised, necessitating the removal of a mass 3 inches by 3½ inches, including the sternal, or costal, extremities of the previously mentioned ribs; all of the gladiolus, save a bit at the inferior end and a slender rim to afford attachment to the left costal cartilages, and a portion of the manubrium. The operation was performed without lacerating the pleuræ costales, the separation between the same and the inner surface of sternum and cartilages being easily effected by the finger. Some hemorrhage from the internal mammary artery was encountered, which, however, was readily controlled. Otherwise, the operation was bloodless. A rubber drain was placed upon the pleural surface, with its exit at the throat, the natural tendency to drainage being in that direction because of a very full chest. The longitudinal wound was united by aseptic silk sutures and aseptic dressings applied."

The patient recovered without an untoward symptom, and without the formation of a drop of pus. The highest thermal rise was to 100.6° F., and the highest pulse-rate, 114. In two weeks she left the hospital for her home, and was soon interested in her housework, though her health has not become rugged.

I can find no reference in my library to excision of the sternum, as thus reported, except in one work, viz., Agnew, vol. ii, page 226. Here the author states that excision for disease should not be performed unless the condition warrants interference. Of course, the bone is very cancellous, and the disease liable to recur, but the operation, in the early stage of even malignant disease, in my opinion, is clearly justifiable.

One point of interest arose in connection with this case before the operation, viz.: Was this sternal growth secondary or primary? At first blush, one would suppose it to be secondary, but the facts that the axilla and mammary cicatrix remained perfectly free from recurrence, and the site of the disease was far from the track of lymphatic infection, would lead one to the opinion that the disease was not secondary. It is true that lymphatics from the antero-central portion of the thoracic wall accompany the internal mammary artery, but the disease under discussion was an outgrowth, primarily, from cartilage, and was not glandular. At first, prior to operation, it was impossible to know whether the neoplasm was a carcinoma or a chondro-osteo-sarcoma; but the pseudo-encapsulated or semi-encapsulated appearance of the tumor, together with the firm attachment to, and involvement of, the cartilage and bone, put the balance of evidence in favor of the latter.

The report of the hospital pathologist, Dr. S. A. Whinery, to whom the specimen was handed for microscopic examination, shows that our surmise was correct, the tumor belonging to the family of sarcomata.

The outcome of this case will be watched with great interest.

The Iowa State Medical Society will hold its forty-second annual session at Burlington, Iowa, and not at Des Moines, as stated in THE NEWS of February 11th, p. 168.

MEDICAL PROGRESS.

Successful Removal of a Perforating Epithelioma of the Calvarium in a Girl of Fourteen.—BRAUN (*Archiv für klinische Chirurgie*, xlv, 1, p. 186) has reported the case of a girl that, at the age of two years, was severely scalded upon the right side of the head, where subsequently a cicatrix formed. At the age of thirteen the girl was struck in this situation with a slipper, and ulceration of progressive character occurred. At the age of fourteen the tumor was excised, and the defect in the skin covered by grafting. The growth, however, recurred, and an ulcer formed upon its surface. The neoplasm was found to be attached to the bone, and pulsation became apparent at its center. No enlargement of the cervical glands could be detected. A section of an excised portion of the mass presented the histologic appearances of epithelioma. It was decided to remove the growth at two sittings. First, the superficial portion was removed by means of a sharp spoon, exposing a defect in the bone almost as large as a silver dollar. The surface was irrigated with a solution of mercuric chlorid 1 : 1000, and covered with iodoform-gauze. The dressings were changed every second day, and at the end of a week the second part of the operation was undertaken. This consisted in the removal of the remaining portion of the growth, and freshening of the edges of the perforation in the bone. Copious hemorrhage took place from the middle meningeal artery, and the operation was temporarily desisted from. Twelve days later an additional margin of bone was removed, the longitudinal sinus was inadvertently opened, and free bleeding occurred, necessitating the employment of an iodoform-tampon. The dura mater was opened and turned back, and after ligation of the pial vessels a thin section of cerebral tissue was removed by means of the thermo-cautery. The wound was covered with iodoform-gauze, and an occlusive bandage was applied. When the dressings were changed a slight prolapse of the brain was found, which increased in size. Some time later recurrence became evident, and the growth was again excised. A second recurrence necessitated repeated excision, after which there was no further recurrence. An attempt was now made to close the large defect in the bone. The surface was first freshened by means of the thermo-cautery, and the subsequent application of an ointment of boric acid. Then a bridge of bone and soft tissues was prepared from the adjacent structures, and applied in the open space. At a later period skin-grafting was practised, and eventually the wound closed entirely, the ultimate result being in the highest degree satisfactory.

Trephining for Intra-cranial Hemorrhage.—ELLIOT (*Boston Medical and Surgical Journal*, cxxviii, No. 6, p. 137) has reported a case of hemorrhage from the middle meningeal artery and one of subdural hemorrhage, in both of which relief was afforded by trephining, controlling the bleeding and removing the clots. In the first case, the patient had fallen a distance of twelve feet upon his head. Consciousness was lost and the pulse became abnormally slow. The pupils failed to respond to light, and the right was dilated. Convulsive movements occurred, and coma set in, with stertorous breath-

ing. No fracture of the skull was appreciable until the scalp had been reflected, when a linear fracture was found, extending from the parietal eminence down to the base of the skull. On trephining, without anesthesia, an extra-dural clot, as large as a small fist, was found, and the meningeal artery was seen spurting in the trephine-opening. The vessel was ligated by passing a curved needle through the dura, and the clot was removed. There was a deep indentation in the brain, in which the blood rapidly reaccumulated until it was packed with gauze. The frequency of the pulse increased from 40 to 100 during the course of the operation, and the patient became sensitive to pain, and moved his arms and legs. On the second day intelligence began to return. The wound healed rapidly and recovery was complete. The second patient was kicked by a horse, and was unconscious for about ten minutes. When seen, three hours later, consciousness had returned, but there was difficulty in speech. The protruded tongue deviated to the left. There was a compound fracture of the skull, two and a half inches above the ear, running upward and backward for two and a quarter inches. The depression was an inch wide and three-quarters of an inch deep. The skull was trephined, and the depressed fragments of bone removed. The dura appeared white and uninjured, but bulged into the wound and did not pulsate. Distinct fluctuation indicated the presence of fluid beneath. The dura was incised, and a quantity of blood was found in the arachnoid space. The hemorrhage continued until controlled by a deep packing of gauze. The patient made a prompt recovery. During convalescence there was slight paresis of the upper lip, and for several weeks the tongue deviated to the left.

Colpoporrhexis—Severance of the Cervix from the Body of the Uterus.—Bidder (*Centralbl. f. Gynäkol.*, No. 3, 1893, p. 40) has reported the case of a nonipara, thirty-seven years old, in which the first and third pregnancies had terminated in spontaneous labor, the children, however, being dead; the second and fourth pregnancies terminated in abortion; the fifth by induced premature labor; the sixth and the seventh by perforation; the eighth was complicated by placenta previa, requiring version and perforation of the after-coming head. The puerperia had all been uncomplicated. The last menstrual period had been in January; fetal movements were first perceived in the middle of June; the first labor pains appeared early in November. Three hours later the amnial liquor escaped. The pains persisted, subsiding, however, after four hours, following a particularly severe contraction. Slight hemorrhage from the vagina was observed and continued for a number of hours. Upon examination the abdomen was found tensely distended and sensitive, the fetus apparently occupying a transverse position, while a sense of resistance, thought to be dependent upon the presence of the fundus uteri, was appreciable above the umbilicus. The fetal heart-sounds were not to be heard. The vagina was large and relaxed. The fetal parts were not within reach of the introduced finger. The conjugate measured about three and a half inches. The patient was anesthetized; and upon the introduction of the hand within the vagina the fetal parts could be grasped; there appeared, however, to be a rupture of the uterus. The body of the child was delivered without difficulty, but the after-coming head had to be perforated and crushed. In view of all of the circumstances it was determined to open the abdomen. When this had been done it was found that the anterior segment of the cervix had been severed from the body of the uterus, an opening of communication existing between the cavity of the uterus and that of the peritoneum. It was now decided to remove the entire uterus. This was done, the wound was closed, and the vagina tamponed. The woman was dismissed in less than three weeks in good condition.

Tracheotomy in an Infant Three Days Old.—Heelas (*Lancet*, No. 3622, p. 195) has reported the case of a well-nourished infant, cyanotic from birth and presenting recurrent attacks of inspiratory dyspnea, with increased cyanosis. The lower jaw was receding and ill-developed, the tongue short, and the palate cleft. Eighty-three hours after birth the condition became suddenly worse, with great lividity of the lips, coldness of the extremities, and general collapse. The short tongue was with difficulty drawn forward, but without affording relief, and an unsuccessful attempt was made to pass a catheter into the air-passages. The child seemed to be dying, and tracheotomy was determined upon and completed without serious difficulty. The opening in the trachea was made below the isthmus and a small-sized india-rubber tube, cut short, was provisionally introduced. The breathing immediately became quiet, regular, and normal, and natural color returned to the lips. The child slept well and took peptonized cow's milk fairly well from a spoon. In a few days a silver tube was substituted for the rubber one. The wound healed well. Respiration through the natural passages was daily attempted; but it was found that, while the child could easily expire and cry out it could not inspire when the opening in the tube was covered with the finger. The little patient continued to do well for nearly three weeks, when symptoms of pneumonia developed, and it was seized with convulsions and vomiting and soon died. After death three ounces of pus were found in the right pleural cavity, with slight consolidation of the right lung. The trachea was normal, except for a small spot of superficial erosion at a point corresponding with the lower extremity of the tube. The tongue was short, but broad and thick. By falling upon the epiglottis, obstruction to the passage of air could readily have been induced.

Rupture of the Small Intestine Caused by a Tapeworm.—Dunlap (*New York Medical Journal*, lvii, 6, p. 166) has reported the case of a woman, thirty-one years old, who, without premonition, was seized with violent pains in the left iliac region, soon followed by prostration. Symptoms of shock were at first not pronounced; but in the course of several hours these became unmistakable and rupture of an ectopic gestation-sac was suspected. A boggy mass was appreciable upon bimanual examination, and this, together with repeated attacks of syncope, seemed to indicate the occurrence of abdominal hemorrhage. When the abdomen was opened, the pelvis was found to be filled with recent blood-clot, while the uterus, ovaries, and tubes were perfectly normal. An aneurism was looked for; none was found. In flooding

the abdominal cavity, to free it of clots, a long tapeworm was floated to the surface. The parasite could be traced to a large ragged rupture in the small intestine. Here there were two bleeding-points, which were secured; but attempts to dislodge the entire worm were unsuccessful. As about two-thirds of the lumen of the intestine was gone (the length of the opening being about an inch and a half), and the edges were ragged and gangrenous, the bowel was resected and the freshened margins united by Lembert sutures. Vomiting continued for thirty hours after the operation, but ceased after an enema of an ounce each of glycerin and magnesium sulphate in a quart of hot water was given. Recovery was thereafter prompt and satisfactory. From the abdomen there had been removed about eight feet of tapeworm, and with the enema there came away seventeeen feet more.

Successful Splenectomy for Wandering Spleen.—At a meeting of the Clinical Society of London, BLAND SUTTON (*British Medical Journal*, No. 1668, p. 1334) reported the case of a woman, twenty-two years old, who had become cognizant of the presence of a movable swelling in the left half of the abdomen, which became the seat of acute pain, with which were associated vomiting and diarrhea. An exploratory operation showed the tumor to be a greatly enlarged, movable spleen, with a twisted pedicle. The pedicle was untwisted and the organ returned to the left hypochondrium. The woman did quite well for some time, but after the lapse of more than three months the swelling reappeared and the patient was suddenly seized with acute abdominal pain, vomiting, diarrhea, and hemorrhage from the vagina. The spleen, at different times, found its way into the most various situations, so that finally it was determined to perform splenectomy. The removed organ weighed sixteen ounces; its texture was normal. Recovery ensued without complication. No difference was observed between the number and proportion of blood-corpuscles before the operation and those after operation.

Sponges for Surgical Purposes.—SIR JOSEPH LISTER (*British Medical Journal*, No. 1674, p. 162) prepares sponges intended for employment in surgical procedures, by washing them first with soap and water, and afterward with sodium bicarbonate; then thoroughly again with water; finally, after drying, they are steeped for a considerable length of time in a solution of carbolic acid, 1:20. After operations sponges are thrown into a tank of water and permitted to putrefy. They are then washed until they no longer discolor the water. Finally they are placed in a solution of carbolic acid, 1:20.

An Additional Bacillus Found in Water.—While studying the water of the river Spree, at Berlin, for the purpose of detecting cholera-bacilli, should they appear, GÜNTHER (*Deutsche medicin. Wochenschr.*, 1892, No. 49, p. 1124) came across a comma-bacillus which, however, he found to bear no relation either to the cholera-bacillus or to the other organisms that have any resemblance to the cholera-bacillus, differing from all in its behavior in culture-media. In a small number of experiments the organisms displayed no pathogenic action. The name *vibrio aquilis* is proposed.

Ischio-pubiotomy.—PINARD (*La Médecine Moderne*, No. 3, 1893, p. 33) has reported the case of a woman, thirty-eight years old, who was tardy in learning to walk early in life, and who presented an oval oblique pelvis, probably with synostosis of the right sacro-iliac symphysis, the antero-posterior diameter being about three and one-quarter inches. She first became pregnant at the age of thirty-two, basiotripsy being required for the successful termination of the labor. Two years later, she became pregnant a second time. Labor was induced prematurely and podalic version performed; the child, however, survived but a short time. In two years the woman again became pregnant and passed through a difficult labor. A year later a fourth pregnancy was terminated in the eighth month, the fetus dying. The woman became pregnant once more and greatly desired to have a living child. Symphysiotomy was deemed impracticable and ischio-pubiotomy was practised at the onset of labor. The horizontal and the descending ramus of the pubis on the side of the ankylosis were sawn through, about two inches from the middle line, and the infant was readily extracted by means of the forceps. The wound in the soft tissues was closed by sutures. By the ninth day it had closed. The woman arose from bed on the twentieth day.

Incarceration of the Small Intestine by the Vermiform Appendix.—At a meeting of the Medical Society of Hamburg, SIMMONDS (*Deutsche medicin. Wochenschr.*, No. 51, 1892, p. 1171) presented specimens obtained from the body of a man, twenty-six years old, who a year ago had had an attack of perityphlitis, from which he had recovered. A few days before his death the man presented symptoms of acute intestinal obstruction and general peritonitis. At the post-mortem examination the appendix was found much elongated, bulbous at its extremity, containing a calculus, and attached to the root of the mesentery. The small intestine had slipped through and was constricted by the loop thus formed.

THERAPEUTIC NOTES.

For Scabies.—A five per cent. solution of creolin may be applied with a brush two or three times a day, followed by a hot bath or a washing with soap at night. Excoriated points are not touched. The application should be repeated once, or oftener if required.—*Corr.-bl. f. Schw. Aerzte*, xxiii, 3.

Arsenic for Epithelioma.—At a recent meeting of the Berlin Medical Society, LASSAR (*Deutsche medicin. Wochenschr.*, No. 4, 1893, p. 95) reported the successful employment of arsenic, in some cases administered by the mouth, in others subcutaneously, in the treatment of epithelioma. The diagnosis was based upon the microscopic appearances. Two cases were demonstrated.

For Exophthalmic Goiter.—

℞.—Ferri et quininæ citrat. . . gr. xxx.
Tinct. digitalis . . . ♏xxx.
Tinct. chirettæ . . . ʒjss.
Aquæ . . . . ad ʒv.—M.
S.—Two tablespoonfuls three times daily, after meals.

THE MEDICAL TEACHER.

THE famous DR. SAMUEL JOHNSON made the following statement: "A Doctor of Medicine is a man who can teach the art of curing diseases. This is an old axiom which no man has as yet thought fit to deny, *Nil dat quod non habet.* Upon this principle, to be Doctor implies skill, for *nemo docet quod non didicit.*"

It is true that every capable and conscientious physician is to some degree a teacher, if not always of the community in which he resides, at least of his patients and friends, in the preservation of health and the cure of disease. Those who contribute useful articles to medical journals are engaged in medical teaching, and so is the qualified medical journalist himself.

But for our present purpose, rejecting the broad definition of medical teaching suggested by Dr. JOHNSON, as well as the more limited one just indicated, let us ask what are the essential qualifications of the teacher in a medical college.

These qualifications are the possession of knowledge, to which constant additions are being made; the power of imparting that knowledge; and having a strong, just, and honorable personality, or character.

In regard to the first qualification, it is obvious that one must first know in order to tell or teach.

This knowledge includes not only the present, but also the past, for that past often includes lessons that are brought forward as new. The words of CICERO: *He remains a boy who does not know what has preceded himself*, have just application in medicine. One who studies professional literature so often meets with illustrations of this puerile condition that he is ready to exclaim with OXENSTIERN, "My son, behold with how little wisdom the world is governed." We could give some instances from recent medical literature of knowledge adduced as new which is really more than half a century old, and of inaccuracies of statements arising from such ignorance, suggestive of the truth of Cardinal NEWMAN'S assertion: "Boys are always more or less inaccurate, and too many, or rather the majority, remain boys all their lives."

In a department of knowledge so progressive as medicine the teacher must be alert that no important step escapes his notice. He must have maturity of judgment, accuracy of reasoning, and breadth of culture; he will not at once accept the new as necessarily true, but prove all things, holding fast to that which is good.

Medicine, once a servile art, and the physician a slave, is now a liberal profession, and, therefore, he who has become a freeman must beware of being subject to the bondage of false opinions and prejudices if he would prove worthy of being a teacher in any of its departments. And in this connection, did space permit, we would be glad to dwell upon the injurious effect that specialism, however greatly beneficial to the advance of medicine, has upon the individual in the unequal development of his intellectual nature, unless this is counteracted by other studies. Let one read what DARWIN wrote at the close of his life as to "the atrophy of part of his brain," to understand what is here meant.

The medical teacher must not only possess knowledge relating to the department he teaches, but he must know how to impart that knowledge to others. To suppose that every man who is thoroughly conversant with a subject can make such exposition of it that the mind of average power will comprehend it is a pernicious and preposterous delusion. As DUPUYTREN has said, the attention must be awakened in order to perceive the most common things, and he who cannot awaken and hold the attention of his auditors fails in public speech; many who hear will

know as little of what he has said as TENNYSON'S "Northern Farmer" did of the parish priest's sermon. As every great picture has in it something which says: Look at me, so every qualified speaker has that in his manner which also says: Listen to me. The thoughts, the images, the knowledge he has, he reproduces as though with pictorial power, so that these are vivid in the minds of others. While such speech must be carefully studied in advance, it is more readily listened to if extemporaneous instead of written; beside, under the stimulus of attentive auditors there will flash out in the fervor of utterance new illustrations, or fresh exposition, as may seem necessary for the perfect understanding of persons as the speaker reads their faces and learns the necessity for further explanation; he has learned the power of thinking when on his feet, to assist previous preparation. HOMER admirably expresses this idea when he says:

> "This man with energy of thought controls,
> And steals with modest violence our souls;
> He speaks reservedly, but speaks with force,
> Nor can one word be changed but for a worse."

Finally, the medical teacher must possess character. By character we mean personal integrity, purity of heart and life, nobleness of impulse and action; one who has these qualities is lifted above sordid and selfish ends, petty intrigues and political management, and regards the highest life as that which does the most good, and continually seeks to attain this ideal.

Such men as J. K. MITCHELL, HUGH L. HODGE, ALONZO CLARK, AUSTIN FLINT, WILLARD PARKER, J. MARION SIMS, SAMUEL D. GROSS, and D. HAYES AGNEW are among many of our famous departed worthies who honored their calling and impressed upon numbers of students in greater or less degree their characters, not only imparting knowledge, but inspiring them to lives of honor, usefulness, and goodness.

VENESECTION IN PULMONARY TUBERCULOSIS.

THERE is scarcely an affection (at one stage or another) in which venesection, like many another useful therapeutic agent, has not been recommended. Nevertheless, there can be no doubt that there are certain indications that are met by bleeding better than by any other measure. There is reason to believe that bleeding has a greater field of useful application than we of the present generation actually realize. In many diseases there occur periods in which the organism were better off for for the removal from the bloodvessels of a fluid that is stagnant and saturated with noxious matters. The suggestion of bleeding in the treatment of anemia seems at first sight paradoxical, but it can readily be understood that under certain conditions bleeding may prove capable of pronounced good. Pulmonary tuberculosis has hitherto been considered one of the contra-indications to venesection. HUGGARD (*British Medical Journal*, No. 1674, p. 171) has, however, presented facts that go to show that in some cases of pulmonary tuberculosis, in plethoric individuals, in which the disease-process is latent, but in which a tendency to hemoptysis exists, relief may be afforded by judicious venesection. As the occurrence of hemoptysis favors reinfection or the recrudescence of a dormant process, the desirability of its prevention is obvious. Venesection should be restricted to those cases of pulmonary tuberculosis marked by recurrent hemorrhage, preferably, but not necessarily, in the first stage, in which there exists a condition of plethora, with a pulse of high tension, and the general health is good, with freedom from marked constitutional symptoms (such as night-sweats, elevation of temperature, and debility). In these cases the occurrence of hemorrhage is generally preceded either by a sense of fulness in the head and a feeling of general heaviness, or by a feeling of unusual well-being. Under the conditions first named, the plethora is probably decided, and the bleeding is likely to be followed by a sense of relief; under the conditions second named, the plethora is probably relative, and the bleeding is followed by some degree of prostration.

ANIMAL PRODUCTS IN THERAPY.

THE use in therapeutics of substances derived from the animal kingdom is not altogether novel; we need but refer to cantharides, to the digestive ferments, and to vaccine; but the developments of a few years past lead in a somewhat new direction and indicate that ere long a number of products of animal origin equal in power and importance to such vegetable derivatives as quinine, strychnine, and morphine will be placed in our hands. The usefulness of the thyroid gland in the treatment of myxedema, and perhaps of some other affections, *e. g.*, cretinism in an early stage; the usefulness of

the serum of dog's blood and of goat's blood in the treatment of tuberculosis; the limited usefulness of pancreatic preparations in some cases of diabetes mellitus, are instances of one aspect of the problem—that of supplying to the organism substances normally present, the absence of which causes disturbance of function, auto-intoxication with katabolins, or lessened power of antagonizing specific toxins. The usefulness, in some cases of pneumonia, of tetanus, and of diphtheria, of antitoxins present in the blood-serum of human convalescents or of inoculated animals, or developed in inanimate culture-media, illustrates another aspect.

Finally, the testicular injections of BROWN-SÉQUARD, the infusion of nerve-substance and similar experiments, while as yet not only inconclusive but applied most unphilosophically, nevertheless indicate that various tissues and juices of animals contain substances of toxic and therapeutic power, which deserve study, and for which important uses may be found.

EDITORIAL COMMENTS.

Germany and the Pan-American Medical Congress.—The Secretary-General of the Pan-American Medical Congress, Dr. Reed, has, with the approval of Dr. Pepper and Dr. Mastin, addressed an open letter in reply to that of Czerny (see THE NEWS, February 11, 1893, p. 165) relative to the participation by Germany in the work of the Congress. Attention is called to the fact that to have attempted an organization in Germany or any other European countries in the interest of the American meeting, would have been in violation of loyalty to the International Congress, while an official invitation to the government and medical societies of Germany and other European countries to send delegates to the Washington meeting would have been almost equally inimical to the interests of the Rome Congress. It was therefore resolved that the organization should be limited to the American countries, and that, while it was desirable to secure the attendance of distinguished confrères from Europe as guests, invitations to that end should be strictly personal in character, and should be issued by the general officers and presidents of sections, at their discretion.

The languages chiefly spoken by the peoples of the various constituent countries of the Congress are Spanish, Portuguese, and English, and these were accordingly selected by the committee as the official languages of the Congress. French, which is the language of important colonies and communities, was subsequently added, at the instance of confrères in Brazil, who employ it largely in scientific communication, as, indeed, do a large proportion of the physicians of both the English- and Spanish-speaking countries. Danish and Dutch are not included, because it is extremely, indeed practically, impossible to deal with them satisfactorily in a literary way in this country. It was hoped that delegates from countries and colonies speaking other than Spanish, Portuguese, English, and French would furnish remarks on papers in one of the official languages. This was so thoroughly understood by the committee and has become such a well-established usage at international congresses, that it was not deemed necessary to state it explicitly.

Arrangements have been made for the special sailing of a steamer on September 9th, directly to Italy, by way of the Azores and Gibraltar, to take those desiring to attend the Rome meeting, a special reduced rate being accorded for the occasion.

Assurance is given that European confrères who may honor the Pan-American Medical Congress with their presence will be accorded every linguistic privilege, that arrangements have already been made for their return to Italy in time for the International Congress, and that in the event of their coming they will be greeted with a most cordial American welcome.

The Quarantine Committee of the New York Academy of Medicine, at a previous meeting had been discharged, as it now appears, through a certain combination of misunderstanding and non-understanding of the true question at issue. A special meeting of the Academy was held on February 24th, at which matters were straightened out and the committee reappointed. The pretext made for discharge of the committee was that in advising concerning sanitary questions not directly connected with the quarantine, the committee had gone beyond the powers committed to it, and that the dignity of the Academy as a scientific body was compromised by what was stigmatized as "politics."

It is fortunate for the good name of the profession and for its influence in the community that the narrower view of the function of the profession was voted down by the sound sense of the members of the Academy. *Nolens volens*, the profession is made the guardian of the public health, and it should decidedly and emphatically be *volens*. Only as it recognizes its public functions and speaks with a determined and harmonious voice upon them can it merit the past legal sanctions bestowed upon it, and bring about the desired extension of privilege and power that should speedily be given to it. This plan of scuttling to the burrows of "calm scientific discussion" in the face of public duty and danger is itself disgraceful politics, arrant nonsense, or neglect of duty —probably all three combined.

Medical Etiquette.—The *Boston Advertiser* concocts, and the *Philadelphia Evening Telegraph* copies, with profound seriousness and assurances of genuineness, a long story of a dying patient being forced to submit to the treatment of a detested physician in charge of "a patient with a raging fever," because, called in in emergency, he would not turn the case over to the family physician, who was desired by the patient and family. Neither would the family physician take charge of the case, because of "professional etiquette." Thereupon the newspaper moralist belabors the whole profession, and argues against giving the regular physicians any further "monopoly." The quacks (and by this is

meant the genuine unadulterated quacks, the wizard kings of pain, for example, and the manupathists) should not be forbidden by law, because the educated physicians by their "rules of etiquette" would most surely become "a huge pool or trust, and an imposition on the public." Were the fact not before our eyes, it would hardly be believed that two highly repectable papers could be brought at this stage of civilization to publish such egregious tomfoolery. Such things hint at the deep-seated, almost ineradicable hatred of the medical profession that so long survives in the public mind.

Butterine in the State of New York.—THE MEDICAL NEWS of January 30, 1892, contained an article by Professor Caldwell, of Cornell University, scientifically demonstrating the excellence and usefulness of oleomargarine. Despite the fact of this excellence, politics has kept upon the New York statute-books a law forbidding the use of this food-product by hotels, restaurants, etc. The law failed to prohibit its use by State institutions. After careful investigation, Dr. Blumer ordered a supply for the Utica State Hospital, procuring the same at seventeen cents a pound, and testifies that it is "a more palatable and acceptable article of food" than dairy butter for which the hospital had to pay twenty-two and a half cents. Although this is a saving of several thousand dollars a year to the State in one institution, the Governor of the State demands an amendment to the law extending the scope of the interdiction to the State institutions.

State Aid for Hospital Purposes.—The University of Pennsylvania asks for help from the State for hospital extension and administration, and gives cogent reasons why the bill for this purpose before the Legislature should be passed. No body of men do for the public the amount of gratuitous work, and no work done is of more value to the community than that performed by the physicians of a properly organized and rightly conducted medical school and hospital. And yet no labor or profession is more inadequately rewarded by the community than this of medicine. With a four years' obligatory course of study, with a limitation and fixation of the professorial salary, and with an administration not aiming at private but at professional and public good, there remains no reason against and every reason in favor of granting the State aid asked for.

A Method of Publishing Hospital Reports Without Expense.—From Michigan comes a very remarkable hospital report. It reminds one of the curious "albums" found in hotels devised by advertisers to get one's eye on the advertisements deftly inserted near other and more (or less) attractive matter. The report is lavish in typographical and engraved work, the advertisements of face masseurs, of manufacturers of crackers, boots, furniture, of dealers in oysters, liquors, etc., occupying one page, and the hospital report the alternate page throughout the volume.

A Four Years' Course at the Woman's Medical College of Pennsylvania.—No student can now enter this college and graduate under less than four years. Thus the oldest school for women has joined the ranks of truly medical colleges in requiring four courses of lectures as essential for the doctorate. The friends of genuine medical education must rejoice, as one after another our institutions recognize the changed conditions and elevated standards demanded by modern medicine and civilization. To those *first* taking the stand of their own free will instead of being driven into it, all honor is due.

D. Hayes Agnew Memorial Children's Ward.—A committee of which Dr. S. Weir Mitchell is chairman, and composed of representative medical men of Philadelphia, solicits contributions for the building and endowment of a ward at the University Hospital as a memorial to the honor of Dr. Agnew. Beds in perpetuity can be endowed for $3000, or annually for $200. Large and small amounts will be gladly welcomed. This is a noble movement and deserves to be speedily and enthusiastically successful.

Regulation of Medical Practice in Connecticut.—A bill is now before the Legislature of Connecticut providing for boards of examination to license practitioners, each of the three "schools" being allowed its own independent board. Five reputable physicians constitute each board, nominated by the State Board of Health upon the recommendation of the medical societies. That even this enactment would be progress and advance upon the condition of the past is a fact suggestive of reflections, wise or otherwise.

The "Canadian Practitioner" is somewhat belated in its appearance for January, but makes amends by presenting itself in a new dress and a new arrangement. The dignity of the *Practitioner* would be increased, we are convinced, if it dropped the practice of interleaving its text with advertisements. Ordinarily it is optional with the reader whether or not he shall consult the advertisements of his medical journal; and he is likely to be offended to have them thus thrust under his nose, as it were.

The New Mesmerism.—The result of Mr. Ernest Hart's investigation of the new hypnotic feats exhibited by the patients of Dr. Luys, of Paris, is, that the patients were "tricksters of the most barefaced kind. Some of them were very clever actors, possessing dramatic powers which might have been turned to better purposes; most of them were utterly venal, and some confessed that they played upon the credulity of Dr. Luys for their own purposes." It is a sorry history, due to the want of good Anglo-Saxon common sense.

Aseptizable.—A correspondent of the *Journal of the American Medical Association* suggests the word *Aseptizable* to describe the character of instruments capable of being rendered aseptic. This would be in harmony with the words *aseptize* and *aseptization*, which are now coming into use. But why not form the word from our perfectly regular form, *asepticize*, and thus have *asepticizable?*

A Truthful Advertiser.—Patent-medicine men do tell the truth sometimes. A recent advertisement in the *Public*

Ledger of this city says: "*There is already a great demand for the specific at the retail drug-stores in Philadelphia*, where about every third man has a cold since the recent blizzard, with more than half a hundred deaths every week. *Mortality from this cause has increased more than 33⅓ per cent. within a month.*" The italics are ours.

The Operation of Unilateral Pubio-ischiotomy, recently applied to a Naegele pelvis by Prof. Adolphe Pinard, of Paris, with entire success to mother and child, if critically examined in the light of the operator's own statement, will be found to be altogether different from that denominated "bi-pubiotomy" by Prof. Gennaro Galbiati, and performed by him on March 30, 1832, in the Incurabili Hospital of Naples. In this case, the conjugate measured only an inch; the bones were divided on each side, and the anterior part of the pelvis lifted up by the passage of child. The fetus was dead, and the woman died of gangrene of the genitalia in four days. In the Pinard case, the conjugate was 8.5 cm. ($3\frac{1}{16}$ in.); the right sarco-iliac synchondrosis was ankylosed; the os pubis on the right side was sawn through under direct incision, and the wound then sutured; the ascending ramus ischii was treated in the same way. In extracting the fetus the left side of the pelvis opened like a hinge and the sawn part of the os pubis separated one inch.

The First Symphysiotomy in London was performed at the London Hospital on February 12, 1893, by Dr. Arthur H. N. Lewars, with entire success. The pelvis of the patient was just a little too small to admit of delivery by means of the forceps after a faithful trial, and pubic section was preferred to craniotomy, which would have permitted an easy delivery, but with a dead fetus. As it was, the section was performed with some difficulty for the want of a proper knife, and one bistoury was broken in the trial. The patient promised to do well. In 116 years symphysiotomy has been performed but twice in England, the first operation proving fatal to both mother and child, because of the poor condition of the subject. This operation was performed by Mr. John Welchman, at Kingston, on September 4, 1782. The case was one of malacosteon in a woman reduced fourteen inches in height, and bearing a dead and putrid fetus.

New Buildings for the Surgical Clinics of the University of Vienna.—Those who have visited the surgical clinics of the University of Vienna must have been struck by the inadequacy of the accommodations for both operator and student. The announcement will therefore be received with gratification, that it has been proposed to begin during the current year the construction of new buildings for the clinical work of Professors Billroth and Albert, which are to be pushed to a speedy completion.

Consultation with "Gentlemen."—"The Code of Ethics must be changed to allow consultations with *all legally qualified physicians* who are not advertisers or abortionists or worse. Any educated man who is a gentleman should be met in consultation without hesitation."—*Lanphear's Kansas City Medical Index.*

Please define the terms "educated man" and "gentleman."

SELECTION.

THE BICHLORID OF GOLD TREATMENT OF DIPSOMANIA.

BEING determined to find out something definite about the matter, early last spring I obtained a position as physician to a gold-cure sanitarium at a distance from the city, and have carefully studied the cure up to within a few days ago. As I have had personal experience in treating about three hundred cases, both in and out of the aforesaid sanitarium, I feel that the few remarks I can make may be of interest to you. And first, I am prepared to give you the formulary of the gold treatment, which is almost, if not quite, the same in all of these institutes, as follows:

No. 1. Tonic. Known in the institutes as the "dope:"

℞.—Aurii et sodii chlorid. . . . gr. xij.
Strychninæ nitr. . . . . gr. j.
Atropinæ sulph. . . . . gr. ¼.
Ammonii muriat. . . . gr. vj.
Aloin. . . . . gr. j.
Hydrastinin. . . . . gr. ij.
Glycerini . . . . . ℥j.
Ext. fl. cinchon. comp. . . ℥iij.
Ext. fl. coca erythrox. . . . ℥j.
Aquæ dest. . . . . ℥j.—M.

S.—1 dram at 7, 9, 11 A.M., at 1, 3, 5, 7, 9 P.M.

No. 2. The injection known in the institutes as the "shot:"

℞.—Strychninæ nitr. . . . . gr. $9\frac{1}{10}$.
Aquæ dest. . . . . ad ℥iv.
Potass. permangan. q. s. to color.—M.

S.—Begin with gtt. 5, which equal gr. $\frac{1}{10}$, and increase one drop at each injection until the physiologic effect is produced. Four hypodermatic injections to be given daily, beginning at 8 A.M., then at 12 M., 4 P.M., and 8 P.M.

No. 3. Used with No. 2:

℞.—Aurii et sodii chlorid. . . gr. 2½.
Aquæ dest. . . . ad ℥j.—M.

S.—Gtt. 3, every four hours, in combination with the strychnine solution, for the first four days.

This last prescription is used only for the moral effect, which is produced in the following manner: Five drops of the strychnine solution are drawn into the syringe, and then three drops of the gold solution are drawn in and mixed. This produces a golden-yellow color, to which attention is called, and the patient is further assured as to the reality of the presence of the gold by the stain left on the skin after the hypodermatic needle has been removed.

A positive disgust is in almost, if not in every instance, produced in the following manner: The patient is given a drink of whiskey, then the so-called bichlorid of gold solution, really a solution of strychnine, is injected in his arm, but at the same time, and without his knowledge, he receives one-tenth grain of apomorphine. It takes but a comparatively short time for the emetic to

produce its effects; more or less violent emesis is produced, and the patient soon associating the in-taking of the whiskey with the subsequent disagreeable and sickening vomiting, acquires a positive disgust for the liquor, and is not able to keep any on his stomach. Now he acknowledges the wonderful power of the hypothetical gold compound, and surrenders unconditionally. He is converted, and from an unbelieving scoffer is changed into a disciple and supporter of the prophet. These are the cases that are the most widely advertised, and that have done the most good for the "Keeley Institute" folks.—CHAUNCEY F. CHAPMAN, M.D., PH. G., *in the Chicago Medical Recorder, February, 1893.*

CORRESPONDENCE.

SOME THOUGHTS ON THE OBSTETRIC EXAMINATION AS TAUGHT BY CREDÉ AND LEOPOLD.

To the Editor of THE MEDICAL NEWS,

SIR: Any method that tends to make the science of obstetrics more exact, and guards the delivery of the mother from those unseen yet potent enemies that seem always on the alert for an opportunity to do harm, must be welcomed by the thoughtful members of the profession. It is hardly possible for everyone to take the same point of view or to agree entirely with dogmatic teachings. Experience frequently shows theories, however attractive on paper, to be absolutely impracticable in every-day work.

The doctrine of thorough asepsis in obstetrics, as well as in surgery, has doubtless saved many lives, and any paper that insists upon this practice must be considered sound, even if we cannot always approve of the methods recommended. Every teacher of the profession must expect criticism; thorough discussion only tending to increase the good results aimed at.

The appearance of an extract in a recent medical journal[1] from the fifth edition of the *Text-book of Obstetrics for Midwives*, by Prof. E. Credé and Prof. G. Leopold, private medical counsellor, laying down with so firm a hand directions so opposite to the views held by a number of the profession in this country, and suggesting some procedures novel, at least to me, leads me with all modesty to present my criticism for the better understanding of the subject.

While the treatise under consideration is ostensibly for midwives, a careful perusal of the paper in question shows that it is intended as well for the instruction and guidance of the medical practitioner.

The obstetric examination is divided by these authors into the external and internal. It is in the former that the methods are novel, and aim to learn so much more of the condition of affairs than is the custom in this country. Inspection, auscultation, and palpation are the means employed. We have hitherto been accustomed to employ these aids to diagnosis, but have never attempted to learn so much as is now claimed to be possible.

The general position and size of the child, the amount of liquor amnii, any deformity of the woman's frame, hernial wounds, etc., we have looked for; but we are now instructed in the use of four manipulations that are intended to supplant almost entirely the internal examination upon which we have depended so much.

In the first manipulation the palms of the examiner's hands are passed gently over the abdomen of the woman, defining the position of the fundus of the uterus in relation to the navel and the ensiform cartilage; whether the child lies vertically or transversely; whether the head or breech lies in the fundus; and the approximate size of the child.

This is, I may say, routine practice, and has little novel about it. The second manipulation has for its object the finding of the back of the child, and calls for no comment.

In the third manipulation the examiner spreads the fingers of the right or left hand as far apart as possible, and "with the thumb and tip of the middle finger seizes the presenting part of the child just above the pelvic inlet."

In very many instances this procedure must be extremely difficult, if not impossible. The natural fat and tense walls of the abdomen offer insurmountable obstacles to the exact determination of the mass felt. It is true that the head of the child can be felt, if there; but it would require a master hand to determine *accurately* the position of head. The difference between the head and the breech could also be recognized, but that "if felt uncommonly covered, indistinct, and somewhat softer than usual, the suspicion is justified that the placenta lies in the lower uterine segment" is rather doubtful. Might it not be omentum or intestines?

This manipulation is said to be of great value when the presenting part remains either in or above the pelvic inlet. If, however, it is in the cavity or outlet of the pelvis, then the fourth manipulation is of importance.

This consists in passing the "finger-tips of both hands slowly and gently from above along the sides of the pelvis *into its cavity!*" This procedure is only equalled by the next, when the pelvis is examined externally: "For this purpose the finger-tips of both hands are advanced from both sides into the *sacral region of the pregnant woman*, there to examine the curves (?) and width of the sacrum, as well as the *direction and mobility of the coccyx*, in order to determine thereby the inclination and *curvature* of the pelvis."

Is it possible for any man to so pass the fingers of both hands into the pelvis of any woman, pregnant or not, through the abdominal walls, as to feel the curve of the sacrum and direction and mobility of the coccyx? Either the German women have very thin and elastic abdominal parieties or the German physicians have great powers of penetration.

I think enough has been quoted to show the novel features of this method of examination. Why all this has been advised, and so much stress laid upon it when the authors proceed to describe the internal examination by means of which all that is aimed at in the new plan can be determined by the old way so much more accurately and quickly, and with certainly less pain and annoyance to the patient, is a question. Nothing can be claimed on the score of modesty, on which stress is laid, even to covering the woman's face, nor can the comfort and well-being of the patient be promoted by this pressing, squeezing, and forcing of the examiner's hands into

[1] N. Y. Journal of Gynecology and Obstetrics, December, 1892.

the tissues of the parturient woman. Besides all this, it undoubtedly lacks accuracy.

Indiscriminate, frequent, and unnecessary internal examinations are properly decried, but it cannot be denied that the safety of the patient is more perfectly assured when the accoucheur is thoroughly posted as to the condition of the vulva, vagina, and pelvis of the mother, and the presentation and position of the child. The method that safely and accurately informs him on these points is the one to follow.

Asepsis of the examiner's hands is demanded, and rightly so, but whether neglect or the careless practice of this precaution lays the practitioner open to the liability of legal prosecution in this country in case the puerpera becomes ill or dies, as it appears to do in Germany, is a question which I am not aware has ever arisen here.

A parturient woman should herself be cleansed externally; but few American women of any class would submit to having the pubic hair cut short, and then be scrubbed every three hours, *at least* for five minutes, with warm water, soap, and brush, then three minutes with a 2½ per cent. carbolic acid solution over the mons Veneris, upper part of the thighs, anus, buttocks, etc.

One internal examination seems to be all the authors allow, claiming that with the continued use of the external, especially the fourth manipulation, no further internal examination will be required. Nevertheless, they insist, further on, that as soon as the membranes rupture a careful internal examination *must* be made to determine whether an arm or the umbilical cord has descended alongside of the head. Here, at least, is something that the external examination cannot discover.

Two statements, which probably more than any other opinions expressed, led to a careful study of this article, were these: "It is nothing less than *criminal* to try to assist in the stage of dilatation by attempting to stretch the cervix with the fingers and to push back the anterior lip of the cervix"; and ". . . for when the os is not completely dilated the lower uterine segment is forced down into the small pelvis, the uterine walls at that point are incarcerated between the head and the bony pelvis, thus causing swelling and inflammation of the margins of the os."

This second quotation is used in speaking of the inadvisability of stimulating pains in the first stage, and is applied here to illustrate a condition of affairs which frequently arises in labors which have not been in the least interfered with. This latter paragraph seems to point so directly to a cause of delay and danger to both mother and child, when the procedure so harshly and so unjustly condemned would be the proper one to pursue, that I addressed the two following questions to five prominent and widely known obstetricians of my acquaintance and append their replies:

1. "Do you consider that it is nothing less than criminal etc., etc. ?"

2. "What would be your course of treatment when the os is not completely dilated, etc., etc. ?"

DR. JOS. PRICE: "Neglect or delay in pushing back the thickened edematous anterior lip of the uterus fixed under the pubic arch, results in needless contusion, sometimes slough, and always in a protracted labor. In multiparæ, with lacerations, with a club-shaped anterior lip, a short posterior lip, the method of pushing the cervix with the broad surface of the right index finger above the pubic arch, and assisting the head clearing during a contraction, is a wise practice. 2. Pushing up the whole anterior circle of the cervix during contraction favors complete dilatation and the head clearing without deep laceration. The practice is a wiser one than multiple incision, also wiser than the premature application of the forceps."

DR. THEOPHILUS PARVIN: "As a rule, all efforts to dilate the os with the fingers in an ordinary case of labor are wrong, and may be very dangerous. Only in exceptional cases do I think such dilatation justifiable. As to the second question, I am somewhat puzzled. Supposing the translation to be correct, and understanding that incarceration does not mean strangulation, I should first employ antiseptic injections of warm water, *e.g.*, creolin or lysol in water, using these abundantly and at brief intervals. Only in case of actual strangulation or threatened uterine rupture would I resort to dilatation, instrumental or digital, or to incisions, or, in case the child was dead, to lessening the size of the presenting part, followed by extraction."

DR. BARTON COOKE HIRST: "I should be sorry to think the procedure criminal, for I have often resorted to it with undoubted benefit, and I shall continue to do so in suitable cases. In reply to the second question, I might do one of several things. I should first try the procedure already mentioned, unless the os was smaller than a dollar, when I would use Barnes's bags."

DR. EDWARD L. DUER: 1. "If it be criminal to assist dilatation by endeavoring to stretch the os with the fingers, I am repeatedly criminal. Indeed, when the os has been previously torn and the anterior lip is caught between the fetal head and the pubic arch, labor comes to a standstill without this manipultion, as I have repeatedly seen. 2. My own practice, when the os is not dilated and the whole cervix is thus compressed by the uterine segment falling into the true pelvis, is, first to give a large hot injection (vaginal) of antiseptic water, wait a short time, then push up the anterior lip quite forcibly above the pubis, between the pains, and endeavor to hold it there when the pain comes on, doing just what Credé and Leopold condemn. Yet from such practice I have never seen aught but good results, and probably have resorted to it hundreds of times. Of course, this may be supplemented by any medication that will quiet and relieve nerve-tension. With the greatest respect, however, for the two great names which endorse the criminality of the procedure quoted, I must have further personal observation of its dangers before considering myself criminal in resorting to it."

DR. HOWARD A. KELLY: "I feel with others that there is imminent danger in handling the cervix with the fingers if the examiner has not previously most carefully sterilized his fingers.

"I do not believe, however, that with sterilized fingers there is any danger. When the blue, congested cervix is jammed down between the head and the arch of the pubis, pushing it back over the head up into the pelvis I consider an important maneuver, not only justified, but requisite under some circumstances."

It is not always safe, as Dr. Hirst said in his reply, to be guided by the dicta of German professors of obstet-

rics, as they live in large hospitals, see nothing of the practice of obstetrics as we know it, only being called in when there is some serious complication. I heartily indorse that opinion, and believe that the majority of American practitioners will continue to use the internal examination as often as seems necessary, and rely upon that, and also assist in the stage of dilatation when the comfort and welfare of the patient require it.

ALEXIS DUPONT SMITH, M.D.

PHILADELPHIA, PA.

NEWS ITEMS.

Pan-American Medical Congress—New By-Laws.—Languages: By-Law IX. Papers may be read in any language providing that authors of the same shall furnish the Secretary-General with an abstract not exceeding six hundred words in length in either of the official languages (English, Spanish, French, or Portuguese) by not later than July 10, 1893, and providing, further, that a copy of every such paper shall be furnished in either of the official languages, at or before the time of the meeting, to the Secretary of the Section before which the same shall be read. Remarks upon papers may be made in any language, providing that members making such remarks shall furnish a copy of the same in either of the official languages before the adjournment of the session.

Publication: By-Law X. All papers read either in full or by title shall be immediately submitted for publication in the *Transactions* (Special Regulation 3), but authors may retain copies and publish the same at their pleasure, after the adjournment of the Congress.

Constituent Organizations: By-Law XI. All medical, dental, and pharmaceutical organizations the titles of which have been transmitted with approval to the Committee on Organization or which may hereafter be transmitted with approval to the Executive Committee by any member of the International Executive Committee, each for his own country, shall be subject to election by the Executive Committee, approved by the President, as constituent bodies of the First Pan-American Medical Congress, and each organization thus constituted shall have the right to designate as delegates all of its members attending the Congress, but no such organization shall meet at the time and place of meeting of the Congress as a distinct body, providing that the Secretary of each such constituent body shall furnish a list of officers and a statement of the number of members of his respective organization to the Secretary-General not later than sixty days before the meeting of the Congress, and shall forward a list of delegates chosen to reach the Secretary-General before the opening of the Congress.

The Section on Medical Pedagogics will devote its attention especially to the history of the development of medical education in America and to the art of teaching.

Dr. J. Collins Warren, of Boston, is the Executive President; Dr. Charles L. Scudder, of Boston, is the English-speaking Secretary, and Dr. Wm. F. Hutchinson, of Providence, R. I., is the Spanish-speaking Secretary.

The Section on Anatomy of the Pan-American Medical Congress will be devoted to the study of human and comparative anatomy and of biology as departments of natural science, as well as in their relations to practical medicine and surgery. Members of the medical profession in Latin-American countries are urged to prepare scientific communications to be read before the section. Much valuable material will thus be collected, and articles of scientific value will find permanent place in the *Transactions* of the Congress. Dr. John B. Roberts, of Philadelphia, is the Executive President; Dr. D. S. Lamb, of Washington, D. C., is the English-speaking Secretary, and Dr. A. M. Fernandez, of New York, is the Spanish-speaking Secretary.

An Army Medical Board will be in session in New York City during April, 1893, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before March 15, 1893, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate of a regular medical college, as evidence of which, his diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing the Surgeon-General U. S. Army, C. Sutherland, Washington, D. C.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXII. SATURDAY, MARCH 11, 1893. NO. 10.

ORIGINAL ARTICLES.

CHOLESTEATOMA OF THE EAR.

BY HARRY FRIEDENWALD, A.B., M.D.,
LECTURER ON OPHTHALMOLOGY AND OTOLOGY AT THE COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE, MD.

The subject of this paper, though long known in medical literature, has only in late years received much attention. American text-books on otology, with few exceptions, mention it in short paragraphs. And while special journals contain many contributions to the subject, it has not been brought sufficiently before the profession in journals devoted to medicine in general.[1] It is needless to add that the subject is not understood by the profession as it deserves to be.

And yet this disease was found by Virchow[2] in nearly one-third of the number of fatal cases of ear-trouble. This fact alone should make it an object deserving careful study. Its many peculiarities, and the ingenious and varying theories as to its nature, add greatly to the interest.

The disease presents itself as a bright, white growth of pearly luster. Its surface is smooth. On handling it readily breaks up into distinct layers, which are placed concentrically over each other. It contains no blood-vessels, and, when examined with the microscope, is seen to be made up of layers of large, flat, non-nucleated, polyhedral cells, which lie stratified in layers that cling more or less firmly to each other. These cells are in every respect similar to the cells of the outer layers of epidermis. Between the layers of cells we usually find cholesterin crystals.

Such growths are found in the middle ear—in the tympanum and in the mastoid cells. They lie in these cavities, which are frequently enlarged, and closely fill them, so as to show accurately the configuration of the cavity in their form. The cavities are smooth, unless they have become carious. They are lined with a very thin membrane, which consists of a layer of periosteum, upon which lies a rete Malpighii, just as in the skin, and which gradually passes over into flatter and flatter cells that finally lose their nuclei and become the flat cells described already. The latter are placed directly upon the lining membrane, which must be regarded as the capsule that surrounds and produces the growth.

This epidermic growth is known as "cholesteatoma," a name given it by Johannes Müller,[1] because of the cholesterin crystals, which he looked upon as the characteristic feature of the growth. It is also called "pearl tumor" (Cruveilhier[2]) or "margaritoma," (Virchow[3]) from its peculiar pearly luster. This it owes to the interference of light by the many fine layers of cells.

The growth varies greatly in size; it may be smaller than a pea or as large as a hen's egg. In practice it is often difficult to decide whether a small collection of flattened epidermic cells in the middle ear is or is not a cholesteatoma.

The growth is most frequently found in the upper and posterior part of the tympanic cavity, but it often extends into the mastoid cells, where it distends the bony cavities by pressure, and where it may perforate the bone externally, or internally, into the cranial fossa. Politzer recently reported a case in which the large growth filled the middle ear, part of the mastoid and part of the auditory canal, and in which it had destroyed the entire internal ear.[4]

Cholesteatoma is often found associated with chronic suppuration of the middle ear, with perforation or destruction of the drum-head, and with polypi of the middle ear. It often develops long after this disease has run its course. But the growth has been found without any other or any previous disease of the ear, and with a normal drum-head. As is well known, it occurs in other parts of the body; it has been found in other cranial bones, in the brain, in the spinal cord, in the mamma, the ovary and the testicle.

The epidermic growth, which we have thus found to form in the tympanic cavity and the mastoid cells, would appear to be a heterologous tumor, for the middle ear is lined by a mucous membrane, which consists partly of columnar and ciliated cells, as in the Eustachian tube, and partly of much-flattened non-ciliated cells.

The explanation of the presence of epidermis in

[1] The following publications are the only ones I could find. Orne Green: Boston, Med. and Surg. Journal, 1881, on Desquamative Inflammation of the Middle Ear. Randall: Journ. Am. Med. Assoc., 1890, on Cholesteatoma of the Ear.

such spaces as the middle ear and mastoid cells is not easily given. Various theories have been advanced. Before we consider them we shall study the clinical aspect as presented by a few cases.

CASE I.—A gentleman, aged twenty-three, first seen March 23, 1891, had had for two months ringing in the right ear and a slight but very offensive discharge. He had had ear-trouble previously, and had been slightly deaf for a long time. Tests for hearing: Watch, 4 cm.; whisper, 0; and voice, 8 m.; Rinné, positive; tuning-fork in Weber's experiment heard in the right ear. After cleaning the external auditory canal, which contained much white, cheesy-looking matter, I found that there was a perforation, about 2 mm. in diameter, in the upper part of the drum, just above the prominent point of the handle of the malleus, known as the short process. The perforation lay in that part of the drum-head called Shrapnell's membrane, or the *membrana flaccida*, from its fine structure. By means of a fine Hartmann canula, which was passed through this perforation, a great quantity of white matter was washed out of the cavity situated beyond. After getting the cavity as clean as possible, it was dried by cotton, and iodoform was then carried into the cavity through the opening. This treatment was kept up at intervals for about four weeks. Less and less matter could be washed out of the cavity, and the discharge ceased entirely; at the last visit the cavity seemed to be perfectly clean; the hearing had improved. The white matter was cholesteatomatous substance.

Perforations in Shrapnell's membrane are not common. They are often found with little or no affection of the rest of the drum, the disease seeming to run its course in the small space in the upper part of the middle ear, between the malleus and the outer wall. This space frequently does not communicate with the rest of the middle ear, or communicates only in the posterior part, so that blind sacs are formed. These perforations are associated with a form of suppurative inflammation which is very chronic, and which, from the proximity to the brain and the thinnesss of the intervening plate of bone, is exceedingly dangerous to life. Their chronicity is due, according to Bezold, to the fact that "stratified epidermis is constant behind these perforations."[1] Many observers have called attention to the frequency of cholesteatomatous masses in the attic (or upper part of the middle ear) in these cases.[2] It is true, that these epidermoid cells often form only irregular masses, while the typical cholesteatoma is composed of regular layers. Nevertheless, it seems impracticable to make a clinical distinction, as it is impossible to find a sharp pathologic difference.

[2] See Kretschmann (Arch. f. Ohrenh., xxv; reviewed in Arch. of Otol., xvii, p. 263), and others.

CASE II.—A young man, aged twenty-one, applied at the City Hospital Dispensary for treatment July 13, 1891, complaining of a discharge he had from the right ear since childhood; which had had its origin in some severe illness (bilious fever?). He had been treated for a long time by different physicians, without any improvement. Several polypi were found, which were scraped off with the curette, and some pieces of dead bone were then likewise removed. After this had been accomplished, a white substance was seen in the upper part of the middle ear. It could not be removed by injection alone, but had first to be dislodged by probes. The large cavity, which was then exposed, was further cleaned, and it was then seen that the whole attic of the middle ear was exposed, the plate of bone forming part of the outer boundary of the middle ear having been entirely destroyed. The ossicula were also lost. At first the patient was treated with a mixture of iodoform and benzoin, but after the cholesteatoma was removed there was no discharge, excepting once for a few days. After removing a small polypus which had returned, the discharge ceased. I then saw the patient at intervals of several weeks for a few months, and at the last examination I found but little epidermis in the water, after washing out the middle ear.[1] He heard the watch on firm contact. His left ear is normal, but there is a small opening in Shrapnell's membrane—as was likewise found in Case I, in the healthy ear. The fact has been pointed out by Walb and by Bezold, that it is not uncommon to find "on one side a perforation of Shrapnell's membrane with suppuration, on the other side a small aperture at the upper pole of the middle ear."[2]

I submitted some of the slides prepared from the matter removed in Case II to Professor N. G. Keirle, pathologist of the City Hospital. He agreed that the substance removed from the ear was composed of typical cholesteatomatous cells.

In Case II we have the cholesteatoma in the same location as in Case I, but it has enlarged, encroached on the walls, and destroyed the outer wall entirely.

CASE III has already been published under the title of "A Case of Extensive Caries and Cholesteatoma of the Mastoid Process, without Local Signs of Inflammation; Death from Thrombosis of the Lateral Sinus and Meningitis."[3] I shall refer only to those points which bear upon the subject under discussion. The patient, a young man, had had chronic suppurative inflammation of the middle ear since childhood. He had many polypi; there was a slight but very offensive discharge. An attack of severe pain came on about the middle of March, 1890, and the patient was not able to work for about five weeks, when he apparently recovered, and considered himself well again. This period of quiet lasted only about five weeks, when pyemia,

[1] Recently the patient again returned to the Dispensary with a slight discharge.

[2] Arch. f. Ohrenh., xxvi, p. 185.

[3] Arch. of Otology, vol. xx, p. 1.

due to erosion of the lateral sinus, suddenly set in, from which the patient died. The *post-mortem* examination, which Professor Keirle had the kindness to make, showed that there was a large cavity in the temporal bone, which had been filled by a cholesteatomatous growth. This cavity occupied almost the whole mastoid process, and had ulcerated this bone both externally and internally, thus opening the lateral sinus. This case shows the extent to which these tumors grow, though, as I have mentioned, they may become much larger still.

In this case there was extensive caries, and the tumor had partly degenerated, especially that part nearest the middle ear.

I wish to mention, parenthetically, that small collections of cholesteatoma were found in the lateral sinus at a considerable distance from the point of erosion.

The three cases related are examples of various degrees of this affection; other cases, similar to them or intermediate in degree, might be described. I shall furnish only one more, which will illustrate the serious symptoms that may arise from the presence of a small cholesteatoma:

CASE IV.—The patient, aged about forty-five years, had had a discharge from the right ear for three or four years. The ear-trouble followed an affection of the throat. During the last year he had had several very severe attacks of pain, which were treated by several physicians with various instillations. When I was called in through the kindness of his family physician, Dr. C. H. Jones (May 6, 1892), I learned that the man had been sick for several weeks, suffering with great pain in the ear and head. When I saw him the pain was so intense that he could not lie down, and he had passed several sleepless nights. The patient had slight fever (100.4° F.). On examination a small polypus was found in the posterior and lower quadrant of the membrana tympani, covered with a little pus. Over the prominent short process of the hammer there was a small perforation about 2 mm. in diameter, very much as in Case I. In this there was likewise a drop of pus. It is necessary to state that the otorrhea had stopped, or was very scant for some time. The ear was cleaned, and the polypus scraped away in great part with a curette. The perforation in the upper part (in Shrapnell's membrane) was washed out by means of Hartmann's canula. This was not sufficient; it was necessary to use bent probes (sharp and blunt ones) and forceps to remove the large flakes which appeared in the opening. In this way a large quantity of dense white scales was removed, which showed the characteristic lamellated arrangement and the pearly luster. Having removed this, steam was applied to the ear, and in a few hours there was a great flow of very offensive pus. At the same time the patient experienced relief.

The ear was cleaned daily in the same way, but in about five days the discharge again decreased, and pain reappeared, especially in the right occipital region, which appeared slightly swollen. In the upper perforation there was some carious bone (malleus?) which seemed to act as an impediment. The perforation was therefore enlarged downward and backward. The opening exposed polypoid masses in the middle ear. The patient improved greatly after this. The opening above was further extended, so as to meet the lower perforation, and the polypi were curetted and treated with absolute alcohol. He continued well for several weeks, during which he used the absolute alcohol. But on June 4th pain again came on, which gradually increased for several days, and the swelling in the occipital region reappeared. The means which had hitherto relieved him failed to give relief, and so he was prepared for an operation.

Operation, June 7th. At the time of the operation the patient was in great pain, and there was great sensitiveness to pressure, especially in the right occipital region, where there was a very general swelling. It was not possible to detect fluctuation with certainty, but I convinced myself that by pressing I could force a drop of pus from the perforation in Shrapnell's membrane. It was decided to open the mastoid process first. The surface of the mastoid was found normal, as was likewise the interior. It was opened to the extent (in depth) of about one cm. It was next decided to make a deep incision through the swelling in the posterior portion over the occipital bone. This opened into a large abscess-cavity, reaching far forward under the sterno-cleido-mastoid muscle. The contents were very offensive pus. A careful examination did not reveal any opening in the bone, which it was suspected lay on the inner surface of the mastoid process. The two wounds were united in the deeper parts, and iodoform-gauze passed through from one to the other. After the wounds had been thoroughly disinfected with a sublimate solution they were dressed with iodoform-gauze.

The subsequent course of the disease was very favorable; the wounds closed very rapidly, without leaving a fistula. The middle ear is now clean and dry; the two perforations which were united are now separate again. There is no suppuration. The patient uses instillations of a 2 per cent. solution of salicylic acid in absolute alcohol.

I have related this case to show the danger of small cholesteatomata in the attic. It is impossible at present to extract any cholesteatomatous matter from the upper perforation with the tympanic canula or with the probe. This by no means renders it certain that there is none deposited there, for we know that this matter is sometimes so tough that it cannot be washed out;[1] yet it is probable that we have removed it.

Let me mention that we find cholesteatomatous matter in other forms of chronic suppuration of the middle ear, in cases in which perforations exist at other parts beside the membrane of Shrapnell.

[1] In a case published by Gorham Bacon, the cholesteatoma would not yield even when exposed to a stream of water, and had to be scraped out. (Arch. of Otol., xviii, p. 391.)

Turning now to the pathology of this growth, one will get but little information in text-books. In Billroth's *Pathology*, cholesteatomata are regarded as sebaceous cysts or atheromata, "especially those that are congenital, on the forehead, temples, or face, filled with a milky or light-yellow pulp, which, under the microscope, shows little beside epidermic scales and crystals of cholesterin."[1] This is not the description of the tumor as we now regard it. It is true that Toynbee[2] looked upon them as such, and believed that they originated in the external auditory canal, but his view has long since been shown to be erroneous.

Virchow[3] describes cholesteatoma as an *epithelial neoplasm*, composed of concentric layers of flat polygonal non-nucleated epidermoid cells, covered with an exceedingly fine capsule; a heteroplastic tumor, whether found in the pia mater or in the bones of the skull. Occurring as it does in mesoblastic tissues, he finds it analogous to *epithelial carcinoma*.

Those occurring in the pia mater are now believed to be formed by the proliferation of the subarachnoid endothelium, due to some unknown irritation. The proliferated cells become flattened by pressure against each other. Those of the mamma, the ovary, and the testicle, develop from the glandular epithelium of these organs.[4]

The views concerning the genesis of cholesteatoma of the ear have been widely different. Various observers have attempted to find the origin of cholesteatomata in the embryonic development of the labyrinth from an involution of the epiblast (Bœttcher,[5] Schwartz,[6] Mikulicz,[7]) or, on the other hand, in an involution of epidermis in the first branchial cleft, which develops into the Eustachian tube and middle ear (Kuester).[8] They would thus be congenital tumors similar in their nature to dermoid cysts.[9]

There is no doubt that Virchow's theory holds good for some cases of cholesteatoma of the middle ear. Of the cases which fall under this head, one recently published by Kuhn[10] may be mentioned. The patient, aged fifty-one years, had never had any ear-trouble, and had been able to hear well till about one year before he was treated. During this year he had at first tinnitus at intervals, and later on dizziness accompanying the tinnitus. On his taking a severe cold, pain immediately set in, with fever and great local inflammation. Twelve days afterward he was operated upon, and a cholesteatoma as large as a hen's egg was found filling the whole mastoid process. This, as Kuhn believes, was in all probability a cholesteatoma which originated in the mastoid process.

A view distinctly different from the foregoing is that cholesteatoma is an inflammatory product from the surface of the mucous membrane, which is retained in the spaces of the middle ear, or the cells of the mastoid process, and by gradual accumulation forms the tumor. This is the theory of Von Troeltsch.[1]

The difficulty encountered here lies in explaining how a cavity normally lined with a mucous membrane can cast off cells of an epidermoid form, and even more, can take on all the characteristics of epidermis with a well-defined rete Malpighii. How are the products of inflammation changed into epidermoid cells? This has been answered in various ways. Troeltsch believed that the product of inflammation (pus), by irritating the mucous membrane, causes a great production of cellular elements, changed in form by the pressure. There are many objections to accepting this view.

Wendt[2] answered the questions in quite another manner. He regarded the epidermoid mass as the product of a desquamative inflammation of the mucous membrane of the middle ear; for this membrane, as he had found, may take on all the characteristics of epidermis when exposed by a large perforation of the drum-head.

It has recently been shown by Schuchardt[3] and others that analogous changes are found in simple ozena, the ciliated epithelium of the nasal cavity being converted into epidermis. The change of laryngeal mucous membrane into epidermoid tissue (*pachyderma laryngis*) as described by Virchow,[4] is to be remembered in this connection, as well as the change which takes place in the mucous membrane, when it is exposed to the air, as in rectal or uterine prolapse or in nasal or uterine polypi: the part exposed to the air becomes hardened and epidermoid.

A novel explanation has been offered by Lucae.[5] Finding cholesteatoma commonly associated with

aural polypi, he was led to believe that there was a proliferation of epidermis on the polypi, and that this, by gradual desquamation, produced a cholesteatoma. In certain cases described by Kuhn,[1] the cholesteatoma was found attached to the floor of the middle ear. It is supposed that these may have been produced in the manner described by Lucae. Another fact bearing on this theory is the discovery by Moos and Steinbruegge,[2] Schwartze,[3] and Weydener,[4] of cholesteatoma pearls in the substance of polypi of the middle ear.

It may not be improper to mention here that Politzer has found cholesteatoma pearls in the substance of the mucous membrane in chronic inflammation of the middle ear, and that he believes that some large cholesteatoma may arise from these.[5]

New light has lately been thrown upon this subject by the researches of Habermann[6] and Bezold.[7] It is shown that when large perforations exist, and especially when the drumhead becomes adherent at the edges of the perforation with the inner wall of the middle ear, or when the tip of the handle of the malleus becomes adherent to the promontory—the prominent portion of the inner wall, which lies opposed to it—(conditions which are very common when the perforations are large), the epidermis or external layer of the drum membrane "gains ascendancy over the mucous membrane, and extends with much greater rapidity over the entire district."[8] This is analogous to the development of epidermis in the bladder, urethra, and kidney from a vesical fistula after an operation for stone.[9]

This fact, which is now accepted by many, is explained by the peculiar lateral growth of the epidermis of the drumhead and external auditory canal, which is seen in the slow migration of blood-specks from the center to the periphery of the drum or the formation of long, rolled-up ribands (Bezold), or of "a membranous diaphragm" in the auditory canal at a distance from the drumhead (Buck)—[10] both being shed epidermis, which owe their form to the "surface motion" peculiar, so far as is known, to the epidermis of this part. The proof that epidermis may extend from the tip of the handle of malleus into the antrum[11]—the most common seat of cholesteatoma—and give rise to such a growth was furnished by a pathologic specimen of Habermann.[1]

Bezold,[2] who accepts this view of the migration of epidermis from the external auditory canal into the middle ear, has lately extended its significance. He is convinced that simple tubal catarrh is frequently the cause of retraction and perforation of Shrapnell's membrane, a fact pointed out by Walb.[3] He believes that the edges of such perforations adhere to the walls of the space within (Prussak's space), and that extension of the epidermis over the walls of these spaces will follow, the cavity will be filled by desquamation—in short, the nucleus of a cholesteatoma is formed. It increases in size, and extends into the antrum. Thus Bezold explains the fact that the antrum and upper part of the middle ear are often the seat of cholesteatoma, and the other fact that cholesteatomatous matter was found in almost all of his cases of chronic suppuration with perforation of Shrapnell's membrane. He does not insist upon this being the only manner in which cholesteatomata are formed, but he holds that many are produced in this way.

Politzer believes that the tendency of the epidermis to extend into the middle ear is much greater at the periphery of the drumhead than in the center, and he calls attention to the fact that cholesteatoma is more common when the perforations are peripheral than when they are central. He describes several pathologic specimens which sustain this view.[4]

There are, then, various ways of explaining the presence of epidermis in the middle ear. It is certain, however, that this alone does not furnish the explanation of the growth of cholesteatoma, but that, as Steinbruegge[5] suggests, there are other unknown conditions necessary for their development.[6] Steinbruegge believes this factor to be a chronic dermatitis. This would ally the affection with desquamative inflammation of the auditory canal and the drum membrane.

If we bear in mind the cases of cholesteatoma that have been reported, without any history of previous inflammation, while, on the other hand, it is certain that many owe their origin to inflammatory affections of the middle ear, we will hesitate to accept any explanation as the only one. As is frequently the case, so here it is probable that the various theories do not conflict, but that each serves

as the true explanation for different cases, or as Kuhn[1] puts it: "Cholesteatoma of the temporal bone is either a true heteroplastic tumor, as Virchow believes it to be in all cases, or it may also develop, and perhaps in many cases, in the course of chronic suppuration of the middle ear, from epidermis which has grown into the tympanic spaces from the perforated drum or the external auditory canal, and which has slowly and continually kept shedding its horny layer, thus forming the stratified cholesteatomatous mass." To which I should add: or it may sometimes result from desquamation of the mucous membrane, which has become metamorphosed into epidermoid tissue (Wendt).

Concerning the *symptoms* and the diagnosis of this disease, little need be added to what is contained in the clinical histories narrated. In themselves the tumors are likely to cause few symptoms, as is seen in the case of Kuhn, and in Case III. (In the latter there was pain, but this was probably due to the purulent collection behind the growth which could not find an exit, and to ulceration of the dura mater.) They often tend to perpetuate an otorrhea or cause its recurrence.[2]

The *diagnosis* can be made when the masses are seen in the middle ear or auditory canal (Case II), or when smaller or larger flakes made up of the characteristic cells are washed out of the middle ear, especially when they are regularly lamellated (Case IV). There are unquestionably many cases of chronic otitis media in which there is slight desquamation of epidermoid cells, but in which cholesteatomata are never formed. Yet I believe that all cases in which such matter is found deserve special attention, and that they must be considered with suspicion when coming from the attic of the middle ear.

The *treatment* has been suggested by what has been said in the clinical histories. It consists in thoroughly and frequently cleaning the middle ear with injections of warm water, which may contain mercuric chlorid (1 : 5000), hydrogen dioxid, resorcin, carbolic acid, etc. The ordinary tip is rarely sufficient to force the steam into the recesses of the middle ear. Special canulas, which are narrow and long and curved at the tip (Hartmann's is one of the best), will enable the operator to reach these parts, even when the perforations of the drumhead are small. In case the opening is too contracted, it must be enlarged. (See Case IV.) When it is difficult to wash out the middle ear through the external auditory canal, we can sometimes succeed with injections into the Eustachian tube, as is recommended by Politzer and others. It is usually necessary to use the probe and the forceps, together with the injection of fluids. Polypi and carious bone must be removed. After the middle ear has been thoroughly cleaned, it is to be dried with cotton and by inflating air, and this is to be followed by the insufflation of powdered boric acid, iodoform, or a mixture of boric acid and salicylic acid (Siebenmann[1]), etc., or the instillation of alcoholic solutions of the same remedies. It is believed by some that we can thus alter the character of the lining membrane, and diminish or prevent the desquamation.

The operation of removing the ossicles has been recommended by Bezold, Stacke,[2] Kretschmann,[3] Kessel,[4] and others; but Politzer believes that this is indicated only in those cases in which "the greater part of the drumhead is destroyed, and there is only a minute portion remaining attached to the malleus, in which cases the malleus and the incus are of no service in hearing. Extraction of the malleus is indicated in only those cases of perforation of Shrapnell's membrane in which caries of the head of the bone has been determined by examination with the probe, or when hearing is greatly diminished. In those cases in which there is slight deafness (as is often the case in perforation of Shrapnell's membrane), extraction of the hammer is to be performed only under urgent circumstances and threatening symptoms, for there is a possible danger of injuring the hearing."[5]

The question of opening the mastoid process is still to be considered. When there is reason to believe that it is the seat of a cholesteatoma, it should be opened. It is difficult to determine this, unless there are local signs. When large quantities of cholesteatomatous matter are found in the discharge, and the process is sensitive to the touch or to pressure, or there is long-continued, deep-seated pain, we can make the diagnosis with much probability. Kretschmann[6] holds that the operation is indicated if the offensive odor of the discharge persists, after removal of the ossicles and irrigation of the attic.

It is important to remember that there is a great tendency for cholesteatomata or cholesteatomatous masses to recur. Patients are to be examined at intervals of a few months for a long time after there is apparent cure.

[1] Arch. of Otol., vol. xx, p. 303.

[2] The compact mass swells when placed into water. There are cases in which very acute and dangerous symptoms have arisen from getting water or steam in the ear and in contact with the cholesteatoma.

THE TREATMENT OF THE INSANE OUTSIDE OF ASYLUMS.[1]

BY FREDERICK PETERSON, M.D.,
OF NEW YORK.

IT is only a short time since in Christendom the insane were believed to be cursed and possessed of devils. In some parts of heathendom, on the other hand, they were supposed to be blessed, in that their souls had been removed by God. Medieval treatment was founded upon that pathology. One portion of the world ducked, whipped, tortured, chained in dungeons, and occasionally burned the insane to death. Upon the whole, the heathen have treated their insane comparatively well.

After a time, many of the therapeutic measures employed by the Europeans of the Middle Ages were abandoned as unsatisfactory. But society still had to be protected; so the insane were fettered in the cells of jails and fortresses, and solitary towers, until a realizing sense of the inhumanity of such treatment struck a responsive chord somewhere in the breast of a Tuke, a Connolly, a Pinel, a Rush, a Kirkbride, an Earle, and doubtless other but unknown immortals, both before and after them. Thus, gradually insanity came to be regarded in the light of a disease, and, instead of prisons, special buildings were set apart for the particular custody of the insane. The great object of the asylums at first was to afford protection to society from lunatics, to protect them from themselves, and to provide for their care and support, when at public cost, in an economical manner. A hundred years ago, however, the asylum was still a species of jail, for its evolution had not yet proceeded far. Dungeons, and iron chains, and staples in stone walls and stone floors, were still in use in many places. Indeed, it is even less than eighty years ago since Norris, a patient in Bedlam (Bethlehem Hospital), in the great Christian city of London, was kept for twelve years in a cell with an iron collar riveted around his neck, and iron bands and rings around his waist, arms, and ankle, the neck being fastened to the wall, and the leg to a rude box of filthy straw.

The asylum having evolved so recently from the prison, it is not strange that it should in some places still possess rudimentary structural appendages and organs which are reminiscent of its embryonal stage; nor is it remarkable that a certain sense of disgrace or stigma has been popularly attached to confinement in an asylum. The people have still to be educated to the idea that insanity is a disease often requiring treatment of a particular nature in the special institutions built for the purpose, and that the asylum is rapidly becoming a pleasant refuge for the hopeless and a hospital for the curable cases of mental disorder.

It is a wise move to change the name "asylum" to "hospital," for it will aid in the diffusion among the people of a true conception of insanity, as now understood by medical men. But there are comparatively few, even in the profession, who are aware of the great improvements which have been made in asylums of late years; how the depressing barren halls and wards and naked floors have given place to pleasantly furnished and carpeted, cheerful-looking parlors, sitting-rooms, and bedrooms; how muffs and strait-jackets have disappeared; how the unintelligent attendant has in many instances given place to the trained nurse; how every new means of treatment is carried out in some places to the best of the ability of the asylum physicians; how schools, employment, theatricals, music, and out-of-door walks are provided in the place of the old deadly monotony, and, in fact, how the asylum has gradually undergone a metamorphosis, until its character has completely changed. There are, to be sure, not many perfectly ideal institutions as yet in existence, but there are some which approach very near to it, as, for instance, that at Alt-Scheritz near Leipzig, and the new asylum at Rome, both of which I visited and described in 1887.[1] These are, of course, constructed on the cottage and pavilion plan, so arranged as to impress one as small colonies or villages, with separate buildings for those merely there for custody because of dangerous propensities, those brought there to be cared for kindly during the remainder of their useless lives, those who carry on various occupations, and finally, for such as enter particularly to secure treatment for the brain-malady which has bereft them temporarily of their reason.

I will say that I believe improvement and reform are constantly going on in asylums throughout the world, that no one is more anxious than are their superintendents to make progress in the care and management of the insane. They are rapidly reaching the best methods of dealing with the insane poor. If any are tardy in this advance, it is because they are so often hampered by the never-ending over-crowding of our public asylums, by the interference of politics, by the lack of money, by the want of a sufficient number of medical assistants, and by a multiplicity of official duties.

While these statements are undoubtedly true, and great credit is due the asylum-physicians of the present day for their strenuous efforts in behalf of their charges, I believe that the *ideal* treatment of almost any insane person is to be sought outside of an asylum. After an asylum-experience of some years,

[1] Read before the N. Y. County Medical Society, Feb. 27, 1893.

[1] "Some European Asylums," Am. Journ. Insanity, July, 1887.

and an experience of many years, too, in private practice, I feel that I am in a position to judge fairly well of the relative merits of treatment in and out of asylums.

Theoretically, it ought to be the right of every individual in sickness to receive the best treatment that medical science affords; but this right can be enjoyed by very few. There are too many interfering conditions. Not every injured man is within reach of the best surgeon, not every fever-stricken one convenient to the best physician, and few are the deaf, the blind, the lame, those with crippled bodies, and those with disordered minds, who ever really receive the best treatment that the world can give. The intelligent doctor and the scientific skill are not the only requisites. Other conditions are good nursing, the most suitable climate, the best hygienic surroundings, the best moral atmosphere. In dealing with affections of the body solely, there is often much to be desired; but it is particularly in the treatment of those who are mentally as well as physically afflicted that so much which should be done is left undone. The obstacles in the way of securing the best treatment are multiplied in the case of the insane by the dethronement of the will, the reason, the judgment, and the emotions.

Just as a hospital is a better place than a tenement-house for a surgical patient, or a case of fever, so is the asylum superior to the home in the caretaking of the pauper and indigent lunatic. The acutely insane of the poorer classes are best treated at present in our large State institutions; and those of the moderately well-to-do, either at home or in the small private asylums. Only the insane of the wealthy classes can perhaps enjoy and carry out ideal methods of treatment, in their own homes, in country-houses, or in foreign travel.

It is, of course, needless to say that there are many degrees of insanity; that there are hundreds of cases that are never obliged to go to an asylum at all; that in society are many insane people carrying on legitimate occupations, and caring for themselves and families; and that, on the other hand, there are cases for which nothing but commitment to an asylum would be suitable or feasible. I have many insane people who visit me at my office, or at clinics, who are regularly following their vocations. Two very insane sisters are private patients of mine. I have described their condition in a paper on *folie à deux*.[1] One teaches music; the other is a book-agent. For twelve years they have been supporting themselves, and laying up money for a rainy day. Another case is in a night-watchman. Another has for years been switching hundreds of trains daily on a great railroad. Another is a young wife with a worthless husband, who cares for the household and supports her children. Another is a bookkeeper; another is a private secretary; another is a superintendent of a manufactory. Two or three are authors of noteworthy books, and support themselves by their valuable contributions to literature. They are all marked cases of chronic or subacute insanity of one form or another. Less noticeable cases at large in society are legion; so that it would be idle to dispute the fact that there are great numbers of insane persons who do not require to be put into custody. Indeed, we should not send any patient to an asylum, unless he needs restraint because of danger to himself or others, or because proper treatment and supervision are difficult in his home, owing generally to poverty or other insurmountable conditions. The sooner a case of acute insanity, occurring in a pauper or indigent, is removed to an asylum the better are his chances for recovery. With cases of acute insanity in those who are able to afford the expense of trained nurses at home, the case is different. It would seem unfortunate to have to send a patient to a large asylum, with its locks, its bars, its associations, its over-crowding, its commingling of the intelligent and the refined with the offspring of the slums, and its inevitable stigma, when the case may prove to be mild, with an early recovery. How much better to make the trial of treatment at home! Naturally, the responsibilities of the physician are often great with an insane patient in a private house, and it is certainly true that the asylum seemingly affords considerable protection from death by exhaustion, suicide, and the like. I say *seemingly*, for this protection is really not as efficient as is generally supposed. From the annual reports of the New York State Commission in Lunacy I gather that the number who die from exhaustion in the public asylums of the State of New York yearly is much over 150, and that the number of suicides of patients committed to their care is in the neighborhood of 15 per cent. These facts are noted merely to show that the asylum is not an absolute protection against the death of a patient by exhaustion from mental disease or suicide, and that in view of this we may treat many patients at home with a clear conscience, and with little greater risk, always providing that the room and the nurses and minor essentials are at our command.

I believe it is not fully appreciated how much the asylum-authorities are striving to do to effect improvement in the methods of management of the insane. Not only is the asylum itself undergoing a metamorphosis, but managers are actually doing all they can to extend the treatment of the insane *outside* of asylums. This is evident, for instance, from the fact of the opening of out-door departments or dispensaries in connection with some of

[1] "Paranoia in Two Sisters." Alienist and Neurologist, Jan., 1890.

them, thus enabling those suffering from mental disorders in the earliest stages, or of the milder types, to obtain skilled treatment without entering the asylum at all, without being deprived of their liberty and rights as citizens. This was first undertaken by the West Riding Asylum in 1889, and has been so successful that it was determined to extend the system to other English asylums (Menston and Wadsley). Not only this, but in Scotland and in some parts of our own country, they actually send their quieter patients from the asylums out to board on farms in the country instead of keeping them massed together in large buildings with their more disturbed brethren. Then, too, some of the large asylums of this country have successfully inaugurated agricultural colonies, several miles distant from the main building, where quiet patients are sent to live in cottages or pavilions "far from the madding crowd." (This plan has been very successful at Kalamazoo and elsewhere.)

In connection with this matter of the treatment of the insane poor, especially of the acute class, another feature was brought up by the author for consideration before the New York Neurological Society, in January, 1890, and in various editorials subsequently, viz.: the admission of the acutely insane to general hospitals. The proposition made was that a law should be passed that nothing in the lunacy statutes should be construed to interfere with the reception and treatment of acute cases of insanity in chartered general hospitals, in the same manner and under the same conditions as patients suffering from other diseases are there received and treated, provided that such hospitals have suitable accommodations, approved by the State Commission in Lunacy. Thus, any of the sixty-five or more chartered general hospitals of this State would be empowered to receive and treat such cases, if they so desired, and every town and city would in this manner be provided with one or several emergency wards for the acutely insane; and who can estimate how much good would thus be accomplished, not only to the particular patients admitted and treated, but to a vast number of other patients, by the training of the nurses, hospital internes, and attending physicians, in clinical psychiatry?

Some fourteen years ago the writer was resident physician in a general hospital with a hundred beds, in a large city. There was no asylum within 200 miles, consequently emergency cases of insanity were sent in from the city and its immediate vicinity to the general hospital for a temporary sojourn. If quiet, they were treated in private rooms; if disturbed, in a pavilion. They were not more difficult to handle, even at their worst, than the cases of delirium tremens that were frequently admitted. This, too, was a hospital not specially arranged for such cases. Those who are familiar with Vienna, Berlin, Strassburg, Bremen, Leipzig, and Paris, and other Continental cities, know that provision is made in many of their general hospitals for acute cases of insanity. Several years ago the Victoria General Hospital opened reception wards for the insane. In connection with the new clinic for mental diseases at Königsberg, a department for the insane was recently opened in the town hospital, so that now every Prussian university (except Kiel) has a clinic for diseases of the mind, in most cases connected with some general hospital.

Nor do we have to go out of our own country to find other instances of the insane occupying wards or pavilions in general hospitals. We have notable examples in Bellevue, in the Marshall Infirmary at Troy, and in the Philadelphia Hospital.[1]

There is the greater necessity for some such provision, as, unfortunately, in almost every town and city of this great Union, except New York City, the jail and the station-house at present serve in the capacity of reception-wards for the acutely insane. It will mark a great advance, therefore, in the treatment of the insane, when general hospitals open their doors and make special arrangements for the reception of acute cases, and their detention for a reasonable period of time, say a month or more, which would in many instances obviate the commitment to an asylum by process of law altogether.

In the largest cities there should be at the disposition of medical faculties a clinic of some kind for mental disorders. This want might, perhaps, be best met by the establishment of psychopathic hospitals on the plan of the psychiatric clinics in foreign universities, small hospitals receiving from fifty to one hundred cases of insanity, provided with laboratories for the study of the physiology and pathology of the central nervous system, ideally constructed in the midst of the city, and fully equipped for the best scientific treatment of patients, and the thorough instruction of students in the elements of psychiatry.

The lines of advance, then, in our care of the insane of the poorer classes outside of asylums are: (1) the opening of special reception-wards or pavilions in general hospitals; (2) the establishment of psychopathic hospitals in large cities; (3) the colonization and boarding-out of the quiet chronic inmates of asylums; (4) the creation of out-door departments in connection with asylums situated in densely populous districts.

When people are sufficiently well-to-do, the ideal

[1] In his last report of the Philadelphia Hospital, Dr. Hughes, the superintendent, speaks glowingly of the advantages to patients of the new system that had just been adopted, of receiving insane patients in special wards. He reports 50 per cent. of cases cured, commitment to an asylum having been unnecessary.

methods of treatment are, of course, to be found outside of an asylum. The insane of this class may be treated at home, or in a seashore cottage, in a country house, or they may go travelling in the charge of a physician and a nurse. The kind of treatment best adapted to the nature of the case must be decided by the physician. The quiet of a private house in the city or country is best for some cases, while the tonic and stimulus of foreign travel are indicated in others. It may be stated that when travel seems to be the prescription required, the greater the change from the environment in which the mental disorder developed, the better. The cities of Great Britain and the Continent do not differ essentially from our own cities, and patients should not be sent to such places with the idea of securing a change of environment. Norway in summer, and Egypt in winter, are regions which offer the greatest inducements in the way of tonics to the nervous system, and stimulus to the mind, and both are at the same time peculiarly restful and calmative.

If these methods of home, country house, or travel are for any reason impracticable, then the smallest private asylum that can be found is to be selected, for the fewer other insane people and the greater number of sane people the patient comes in contact with, the better will be his chances for recovery. There is a need for physicians in practice in the country who will be duly authorized and empowered by law to receive in their own homes and care for one such patient. The chief drawback in home-treatment, if long continued, is usually the bad effect of association with an insane person upon other members of his family, particularly if they be neuropathic. With a sufficiency of nurses and room, there is no contingency in the treatment of the insane that cannot be guarded against. These being provided, the worst features in a case, such as violence, homicidal and suicidal tendencies, attempts at self-mutilation, etc., may be as well avoided outside as inside of an asylum. There are cases in which, though I am opposed to mechanical restraint in great measure, I should employ long-sleeved night-gowns, or even camisoles, rather than let them go home before all means of cure had been tried at least for a few weeks' time.

The conditions and propensities that we have to combat are many. The choice of method must be the result of careful deliberation, and after judicial survey of all the features presented. We usually need the assistance of skilled and experienced nurses. Thanks to the asylum training-schools, there are numbers of such trained nurses of both sexes to be had in our large cities.

In acute cases, whether of mania or melancholia, it has been my experience that confinement to bed is a valuable factor in cure. Hence, on being called to such a case, I have the patient put to bed. Due precautions are taken as to the removal of all sharp instruments, weapons, drugs, cords, door-keys, and the like, and by a simple device the windows so arranged that they may not be opened beyond six inches; otherwise the furnishings may be left as they are without attention.

Insomnia and mental and motor excitement most frequently demand our best skill. In emergency, I am in the habit of using duboisine sulphate hypodermatically in the dose of one-hundredth of a grain, or sometimes hyoscyamine, or hyoscin hydrobromate in doses of from one-hundredth to one-sixtieth of a grain hypodermatically, though these latter are not as satisfactory as duboisine. But for routine treatment of insomnia and maniacal excitement I much prefer hydrotherapy to drugs. In some cases the prolonged warm bath (70°–90°) for from one-half to two hours may be used, but in all cases the hot wet-pack is applicable. For full details as to these procedures I would refer to my paper on "Hydrotherapy in the Treatment of Nervous and Mental Diseases."[1] Sometimes when the wet-pack does not suffice to quiet fierce maniacal excitement, I use duboisine in addition, or give doses by the mouth of paraldehyde or sulfonal, both of which are valuable hypnotics.

In acute depressed conditions, on the other hand, opiates usually act best in cases in which hydrotherapy does not subdue the insomnia, distress of mind, and disordered nervous system. Among opiates, codeine seems to offer advantages over others, and the contraction of a habit need not be feared. The refusal of food is another element of danger. Acute insanity, besides rest in bed, quiet and repose, needs overfeeding to balance the great waste of tissue going on in the system. While many cases of acute mania will eat and drink ravenously at times, from the nature of things their actions are uncertain, and the nurse should be instructed to feed the patient almost hourly and keep account of what is given. Milk, raw eggs, meat-juice, and occasional stimulants, must in extreme cases be our chief reliance. Having an intelligent and assiduous nurse at hand, the necessity of feeding with a tube will only rarely occur. When required, the soft rubber stomach-tube may be introduced by the physician through the mouth or nose, a funnel attached, and the liquid mixture of the substances named allowed to flow in. I cannot here refer to many other morbid conditions that must be met by appropriate medication, and by moral treatment as well in acute as in subacute and chronic forms of mental disorder. There are cases (some of the insanities of puberty

[1] American Journal Med. Sciences, February, 1893.

and adolescence, and other forms) in which anaphrodisiacs modify distinctly the trend of delusions. There are cases in which intestinal antiseptics achieve noteworthy results; indeed, the instances are few in which attention to morbid states of the alimentary canal is not rewarded by considerable benefit to the mental condition of the patient. Arguments with patients upon delusions more or less fixed in character, often has, despite the opinions of numerous alienists to the contrary, decided value in altering their beliefs, and at times even eradicating their insane ideas altogether. It is true that occasional argument is generally of no avail. Such moral treatment must be sedulously and perseveringly employed, daily and for weeks or months, to insure success. Argument is a species of suggestion.

In closing, I cannot but look forward to the time, which passing events foreshadow, when insanity will be recognized as a disease of the brain by the laity as well as by the medical profession; when more of those thus afflicted will be treated in their own homes, and still large numbers in psychopathic and general hospitals; to the time when our present large aggregations of the insane will be disseminated in farm-houses and colonies, and the huge structures now containing them be disintegrated into smaller buildings regularly distributed over large grounds on the community or village plan.

201 WEST FIFTY-FOURTH STREET.

PYLORIC OBSTRUCTION.[1]

BY H. TUHOLSKE, M.D.,

PROFESSOR OF SURGICAL PATHOLOGY AND CLINICAL SURGERY IN THE MISSOURI MEDICAL COLLEGE; CONSULTING SURGEON TO THE ST. LOUIS CITY HOSPITAL; SURGEON TO THE ST. LOUIS POLYCLINIC AND HOSPITAL, ETC.

IN order to discuss with any promise of success the treatment of pyloric obstruction, it would appear urgently indicated to pass in review its possible causes and our means and methods for an early diagnostic recognition. Like other important organs in the body, the stomach is becoming more and more the subject of a direct physical and chemical examination, and it is desirable that an exact recognition of its physical conditions should, as in other organs, be followed by successful direct treatment of a medicinal or surgical character.

The causes of pyloric obstruction are almost always of an intrinsic character; exceptionally only is the condition due to adhesions outside of the stomach, or to growths which from without mechanically press upon the pylorus, and rarely to acute flexions or twists.

The intrinsic causes are: contracting cicatrices of gastric ulcers, the rare submucous proliferation of the connective tissue interfering with its dilatability, and finally, the presence of a malignant growth.

As long as the examination of the tongue constituted the only or principal means of study of stomach diseases, a differential diagnosis was reached at so late a stage of the disease that surgical interference was out of court, or fatal.

Sooner or later all forms of pyloric obstruction give rise to dilatation of the stomach, vomiting at variable periods after food-ingestion, fermentation of stomach-contents, constipation, and emaciation.

The fact of the dilatation can be easily recognized by percussion, by the stomach-tube being felt through the parietes, and by filling of the stomach with gas or, preferably, water. Gastrectasia from atony of the gastric musculature, by its own history of chronicity, of gastric catarrh, of excessive eating and drinking, and of its great curability by lavage, is readily excluded, and the diagnosis of dilatation of obstruction arrived at.

Whether the two following tests constitute actual demonstrations of obstruction I am not able positively to assert, but they are surely corroborative and of value. Ewald recommends the giving fifteen grains of salol, which in the stomach remains inert. In the intestine, by the action of the alkaline juices, it splits up into carbolic and salicylic acids. The absence of salicylic acid in the urine would show that the salol had not passed the pylorus, provided the kidneys are acting normally. Another test is as follows: An ounce of oil introduced into the stomach, and recoverable some hours later by the siphon stomach-tube, would mean impassable obstruction of the pylorus.

Cicatricial obstruction brings the history of preceding ulceration, known by its dull, continuous pain and its paroxysmal increase upon taking food, its bleeding, by its occurrence in the comparatively young, in the chlorotic or anemic, and its gradual healing. In gastric ulcer, according to Riegel, the acid constituent of the gastric juice is greatly in excess; and in dilatation due to cicatricial obstruction, free hydrochloric acid will generally be demonstrable. The absence of free hydrochloric acid from the stomach in pyloric obstruction (the meal-tests of Leube and Ewald having been observed), demonstrated by the Günzburg phloroglucin-vanillin test, would be strong evidence of carcinoma ventriculi.

With advanced emaciation a pyloric tumor becomes discernible, and with it, generally, exceeding dilatation of the stomach and enormous displacement will be noticeable. In one case upon which I operated the pylorus was felt three inches below and to the right of the umbilicus; in another, also the subject of operation, the tumor presented in the

[1] Read before the St. Louis Surgical Society.

left, and was readily moved across to the right iliac region.

The modern methods of examination of the stomach, as taught by Leube, Einhorn, Günzburg, Riegel, Oser, and others, bring us nearer to an exact diagnosis of its diseases. In cases of legitimate doubt, an exploratory operation should be urged upon the patient.

Pyloric obstruction from any cause, if not relieved, leads to the death of the patient. No medicinal treatment is curative. A great deal may be accomplished for the relief of the patient's sufferings, and the prolongation of life. The most promising of all remedies is the emptying by washing of the stomach every second or third day, by means of the soft-rubber siphon stomach-tube; the patient's diet should be rigidly limited to food capable of being absorbed by the stomach, and, with its reduced digestive power, predigested food would appear indicated. The abstaining from stomach-feeding absolutely for a few days at regular recurrent intervals of three or four weeks, and the substitution during that time of rectal alimentation, will distinctly benefit the patient.

Pyloric stricture, however, is a surgical disease, and, as Senn tersely puts it, can be successfully dealt with only by surgical means. In a paper (THE MEDICAL NEWS, May 10, 1890, p. 503) on the subject of "Pylorectomy and Gastro-enterostomy for Pyloric Obstruction," I gave a fairly full account of the fact that the general consensus of opinion of surgeons was against the utility, and of some against the legitimacy of pylorectomy for malignant pyloric stricture.

To re-state the position, I will quote from my former paper:

"In Mr. Greig Smith's classical work on *Abdominal Surgery*, page 392, we read:

"With these results before us, we must admit that if pylorectomy is to be considered anything more than a mere 'surgical exercise,' it is to be contemplated only in a very carefully selected class of cases. If the patient is not in fairly good condition, if the stomach is greatly dilated, if the growth is large, fixed, and displaced, the operation should not be contemplated. And even when the opposite conditions are present, it is doubtful if it could ever be a surgeon's duty to advise the operation; he ought to undertake it only at the patient's urgent request, and after fully and honestly explaining to him the hazardous risk which he undergoes."

The inadequacy of the statistics on the subject may be readily appreciated by a reading of the section on the "Surgery of the Abdomen," by Mears, in the *Annual of the Universal Medical Sciences*, for 1889, page 25.

Professor Buchanan, with regard to the propriety of performing the operation in carcinoma, quotes the opinions of Butlin, and of Billroth, as given by his assistant, Salzer. The former says:

"The excessive mortality due to the operation; the rapidity of recurrence in what have appeared to be most favorable cases for operation; the return of the symptoms of obstruction in some, if not in many, of the cases, and the fact that there does not appear to be one case which can be claimed as a genuine cure, lead me to doubt whether the operation of resection of the pylorus for cancer is ever a justifiable operation."

Salzer states that "Billroth does not only consider the operation of resection of the stomach a justifiable one, but he continues operating with good results in many cases. Of course, he does not operate in cases of carcinoma, if there are already infiltrations and adhesions to the liver and pancreas. In these cases he prefers Woelfler's operation of gastro-enterostomy."

Statistics seem to show but little improvement since the foregoing was written, and I will now quote from Senn's admirable and hopeful paper, "On the Surgical Treatment of Pyloric Stenosis," published in October, 1891:

"At the Berlin International Medical Congress (1890), Billroth gave an account of twenty-seven pylorectomies, all of which were performed either by himself or his assistants. Of this number twelve recovered from the operation, and fifteen died. Of thirteen pylorectomies for carcinoma which survived the operation, five died after ten months, and one after five years and three months after the operation, from recurrence. There were yet living three women at the time the report was made, of whom two had been operated upon two and one-half and four and one-fourth months previously. Of six resections of the pylorus for cicatricial stenosis, three recovered."

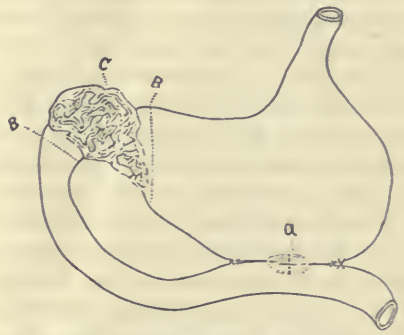
A careful study of most of the recorded cases makes apparent the fact that, almost always, operative procedures were resorted to in patients in an advanced stage of the disease, and in a condition of utter exhaustion. May we not hope for better results with an early diagnosis and an improved surgical technique? When the growth is still limited to the pylorus, and is perhaps of the annular kind, with no secondary involvements or adhesions to other viscera, and the patient is in fair condition, I believe the removal of the growth to be as legitimate and as surely indicated as that of malignant growths elsewhere. Pylorectomy, the Billroth operation, in the hands of its most able and skilled advocates, requires from two to three hours for its performance, and most patients so operated upon die in shock. An operation requiring less time, and fairly accomplishing the same end—that is, the radical removal of the growth—should have some claims for careful consideration. The operation referred to will be best understood in connection with the following case.

(An account of the operation, performed for the first time in March, 1890, was published in THE MEDICAL NEWS of May 10, 1890, and was followed by the publication of two cases by Bull, of New York.)

Mrs. B., fifty years of age, married, the mother of six children, German by birth, had suffered for some months with disease of the stomach, when she presented herself for treatment in March, 1891. She had lost considerable flesh, but was not extremely emaciated. She vomited large quantities of food every thirty-six or forty-eight hours, had no appetite, and was constipated. Physical examination revealed great dilatation of the stomach, and the pylorus movable in the left iliac fossa. A woman of exceptional nerve, she readily consented to an operation. I had proposed a gastro-enterostomy after Senn's method, and thought of following it in a few weeks by a pylorectomy. I made an incision over the tumor, which I had pushed to the median line, and found the pylorus free of adhesions. I then drew forward the stomach, found without much difficulty the jejunum, and placed both in easy apposition upon the parietes, with sponges packed underneath and warm aseptic towels around them. I selected a place four inches from the pylorus on the anterior surface of the stomach (that distance, in view of the later pylorectomy) and two inches above the omental attachment, made an incision an inch and a half in length through the coats of the stomach, introduced my finger into the cavity, examined the pylorus from within, and found it almost impermeable. I then made an incision of the same length into the free margin of the jejunum, and completed the operation by Senn's method, which needs no further description. The patient recovered nicely from the operation; vomiting persisted for three days, and then gradually ceased, and the patient commenced to improve in general health. Two weeks after the operation the patient contracted grippe-pneumonia, which made her very ill; nor did she recover from its effects for eight weeks. With her gradual improvement she became very urgent for the second operation, and insisted upon having that lump, which she could feel in her belly, removed. Three months after the gastro-enterostomy, with the patient in fair condition, I removed the pyloric tumor. A careful examination showed no extension of the disease. I separated the great omentum along the greater, and the gastro-hepatic omentum along the lesser curvature of the stomach, by cutting between ligatures introduced with the blunt needle. The ligature was cut at the loop, one thread drawn toward, the other from the stomach, until separated an inch from each other, when each was tied and the intervening omentum cut. A clamp was applied to the duodenum an inch from the growth, and another one to the stomach somewhat further away. The isolated tumor was now cut off with the scissors. I then closed both stomach and duodenum by interrupted sutures passing through all the coats, then invaginated each end, turning the ends in about one-half inch each, and closed by interrupted Lembert silk sutures. The patient made an uneventful recovery.

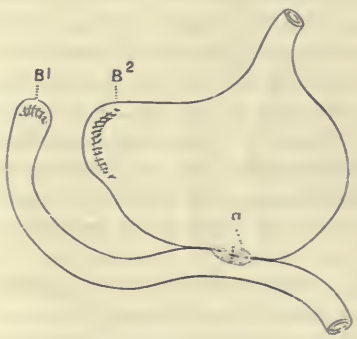
The accompanying cuts fairly illustrate the operation.

FIG. 1.



a. Anastomosis complete.
B, B. Lines of excision.
C. Malignant growth.

FIG. 2.



a. Anastomosis.
B^1. Closed end of duodenum.
B^2. Closed pyloric end of stomach.

The occurrence of more or less regurgitation of food during the first six days was somewhat disturbing. On the tenth day after the operation the patient sat up in bed and was photographed. She remained in the hospital for five weeks longer, and left because of the excessive heat. I heard nothing of her for some little time, when, in October following, my assistant, Dr. Perkins, was called to see the patient. She was having an attack of vomiting and purging, caused by some improper food; a baby and an older child in her family were similarly affected. They all died within forty-eight hours of the attack. Dr. Perkins with Mr. Deutsch, a senior student, secured a post-mortem examination, and I now possess the specimen of the stomach and bowel. There is nowhere visible a return of the disease, and a careful search in the abdomen revealed no glandular enlargement or other secondary involvement. The specimen, however, teaches a very important lesson. The opening between the stomach and bowel had grown very small, until there remained only a small fistula through which we could pass a lead-pencil.

Each of the operations did not occupy more than

thirty-five minutes, and might, with more practice, have been performed in less time.

I believe the operation by making a gastro-enterostomy, allowing the patient to be well nourished and strengthened, and following in about three weeks by pylorectomy—or, in other words, "in two stages"—will give the patient a better chance, and that in malignant growth of the pylorus, limited, recent, and without adhesions, we may secure encouraging results. The contraction of the gastro-enteric communication should be guarded against by much larger incisions, probably from two and a half to three inches long. The incision in the stomach should not be parallel with the greater curvature, but the anterior wall should be cut diagonally, so that the contracting muscular fibers shall pull in every direction from the opening. It may be that the cutting out of a narrow elliptical piece would meet the indication still better. In malignant growths of the pylorus, in an advanced state, with adhesions and secondary involvements, gastro-enterostomy after the method of Senn will afford the patient some prolongation of life and some comfort. If not postponed until too late, the operation should not be followed by a high rate of mortality.

In Greig Smith's, in Jacobson's, and in Treves's latest works the operation of curetting the pylorus has found a place. As an adjuvant to gastro-enterostomy some little benefit may be derived from it, although the increase of the danger of the operation would hardly warrant that procedure. It is not likely to find any followers.

Pylorectomy should never be performed for non-malignant obstruction, as better and less dangerous methods have been devised, and some of which seem to promise well. Digital dilatation of the pylorus after gastrotomy, according to Loretta, has been resorted to some forty times, with improvement, and some recoveries have been reported. The *cure* of the stricture by forcible dilatation seems to be an exceptional result not secured in any other organ. With a longer period of observation we shall probably learn of a good many relapses; nor is the danger of laceration of the peritoneum and of adhesions to be underrated. The coming operation for cicatricial pyloric obstruction seems to be the Heineke-Mikulicz pyloroplasty. It promises greater, if not complete and permanent restoration of functional capacity, without being apparently more dangerous than Loretta's digital dilatation. My knowledge of the operation being entirely theoretic, I take great pleasure in quoting Dr. Senn, who has twice performed pyloroplasty and with the best results:

"*Pyloroplasty.* The safest and functionally most efficient operation for cicatricial stenosis is the one devised by Heineke and Mikulicz nearly at the same time. It is a procedure which well deserves the name it bears, pyloroplasty, as it not only removes the mechanical obstruction, but, at the same time, creates a new pylorus. This operation was first planned and practised by Heineke, of Erlangen, and eleven months later Mikulicz, ignorant of Heineke's work, made the operation in exactly the same manner. The operation is made by cutting the anterior wall of the strictured pylorus and extending the incision about an inch toward the stomach, and the same distance in the direction of the duodenum. The straight incision in the long axis of the pylorus divides the stricture, and the contracted pylorus becomes the posterior wall of the new pylorus by retracting the margins of the wound on each side, at the center, with tenacula, and suturing the wound in an opposite direction to the incision—that is, transversely to the long axis of the stomach. The new pylorus is made up of tissue taken partly from the anterior wall of the stomach and partly from the duodenum, the posterior wall being composed of the narrow contracted pylorus. In suturing the wound it is advisable to tie the sutures from each angle of the wound, tying the central sutures last. Two rows of sutures, deep and superficial, are employed, the same as in closing a wound of the stomach or intestines. Recurrence of the stricture is a physical impossibility, as the new pylorus is composed mostly of healthy tissue, and the danger attending the operation is not greater than that which accompanies an ordinary intentional wound of the stomach or intestines. The results of this operation, obtained in eight cases which have so far been reported, have been very satisfactory, both in reference to the immediate effects of the operation and the functional results."

In reviewing our resources for the surgical treatment of pyloric obstruction I am forced to the conclusion that, for malignant stenosis, free from adhesions, free from secondary involvements, and of recent date, gastro-enterostomy by the method of Senn, followed by pylorectomy as described and carried out by me, to be the best operation, and it will remain so until a more rapid method of pylorectomy will have been devised. If the method of Maunsell, of New Zealand (*American Journ. Med. Sciences*, March, 1892), be found to sustain the claims of its author, there seems to be some hope in the near future of a further improved technique.

For malignant stenosis, with adhesions and secondary involvements, gastro-enterostomy alone seems to be most available.

For cicatricial or non-malignant stricture of the pylorus, the operation known as the Heineke-Mikulicz pyloroplasty contests successfully, I think, with Loretta's forcible dilatation.

In referring once more to my paper published in 1890, and containing the report of my first case, I find that I have stated the same conclusions, and later developments have not changed the position I then took.

A TOPICAL TREATMENT OF BRONCHITIS.[1]

BY EDWIN J. KUH, M.D.,
OF CHICAGO.

DURING the last two years I have employed a method in the treatment of acute and chronic bronchitis, which, in point of both rationality and success, seems superior to all other methods known to me.

The first suggestion was received through an article by William Murrell.[2] As early as 1874 Murrell wrote an article in the *Lancet* on "Ipecacuanha Spray in Winter Cough and Bronchitic Asthma." This paper was followed by various others describing the successful use of this treatment both in England and America. Intermediate to these articles Murrell published similar ones in the same line of observation. His method can briefly be described as follows: Ipecacuanha wine was diluted with twice its bulk of water; inhalations were practised by means of either a steam spray or a double-bulb atomizer; the latter was principally used. Patients were made to inhale for about one-half hour, and as much as four drams were used. As a rule from 100 to 260 compressions of the hand-bulb were required, 100 squeezes being equivalent to about one dram of the fluid. It immediately becomes apparent that this method is too awkward for extended use, although Dr. Murrell publishes very successful experiences with over 200 patients. The ipecacuanha spray, as he himself states, occasionally nauseates and augments the dyspnea in bronchitic asthma.

After prolonged trial I abandoned both the alcoholic and watery sprays and used only oily menstrua. Alcohol and water choke off the breath in the method which I am about to describe.

I apply direct inhalation from what is known as Davidson's atomizer No. 65, which is connected with an air-tank of about thirty pounds pressure. This atomizer emits a very fine and copious spray. The tip is introduced into the mouth in the same manner as in laryngeal and tracheal treatment. The patient is instructed to make as prolonged an expiration as possible, to pause for a moment, then to begin inhaling gently and slowly, and then more rapidly and deeply; during inspiration the spray is started slowly, and then with more or less force, the patient thereby drawing the vapor into his lungs. The successful result of this method depends upon the skill with which patients inhale. Not all persons are able to inhale correctly without more or less practice. The spray must be forced from the atomizer and be actively drawn down into the chest; a mere patency of the glottis is entirely insufficient; the method is a failure if this is not insisted upon. In correct inhalation you can see the spray drawn down into the chest, just as a strong draught will draw smoke into a chimney. If you see vapor suspended in the mouth and throat the inhalation is imperfect. The spray evidently forms a moist coating in the tubes, and but a very small quantity is again exhaled. Severe fits of coughing will expel small additional clouds of vapor, but almost all of it remains in the chest. This method of inhaling must be distinctly separated from the well-known ones from steam or vapor atomizers, of which latter most throat specialists are in possession in one form or another. The usual steam atomizers and vaporizers in use have a far more limited efficacy because they are milder applications.

The composition of the spray to be used can, of course, be varied according to the exigencies of the case or the preference of the physician. No spray, I believe, will be very effective without the presence of menthol. The formula which seems to have been most useful to me consists of: Menthol, from 1 to 2 per cent.; creasote, 1 per cent.; camphor, from ½ to 1 per cent.; oil of eucalyptus, 2 per cent.; oil of pine needles, 2 per cent. in albolene or benzoinol. The average quantity to be inhaled is two drams. Patients then begin to gag and the stomach revolts against more. These two drams are, in well-trained patients, absorbed in about eight or twelve inspirations.

The sensation of the spray extends over almost the entire anterior portion of the chest. It is described as either cooling or warming. Many patients feel the sensation extend to the diaphragmatic line. It causes some hot smarting in and above the larynx. I have never seen it cause laryngeal spasm when deeply inhaled. It does not seem at all unreasonable to assume that so vigorous a treatment, extending probably into the finest ramifications of the air-tract, and in a mild sense flooding them, might possibly injure. But this has never yet, in my experience in hundreds of treatments, been the case. It is possible to train intelligent children in this treatment. My youngest patient was three and a half years old.

The results are most striking in the severest cases of chronic bronchitis; the severer the case the more palpable the result. I refer principally to those cases with tenacious, thick, yellowish, or greenish bronchial discharge, with or without dyspnea. It is astonishing with what almost instantaneous success practically incurable patients with an old bronchitis complicated with emphysema, an anxious, sallow face, and wheezy respiration, will improve. The inhalation in these cases is generally (especially in the beginning of the treatment) followed by a succession of explosive coughs and a mouthful of hereto-

[1] Read before the Chicago Medical Society, Feb. 13, 1893.
[2] Wood's Medical and Surgical Monographs, August, 1890.

fore unremovable phlegm; the spray seems actually to scoop out the secretion in these cases. These patients, who found it impossible to rest in bed, will, within a week, enjoy comparatively peaceful sleep. From week to week a greater permeability of the smaller tubes can be noted by auscultation. The phlegm gradually loses its purulent character and becomes mucoid; it also decreases so much in quantity that even during the inhalation very little, or none, can be raised.

In the few cases of bronchitis complicating chronic nephritis and diabetes under my observation, the results were equally gratifying. We must consider the circulatory and other changes in these diseases as predisposing to bronchitic infections. The maximum results in chronic bronchitis are generally obtained within the first two weeks of treatment; after that the amelioration progresses at a slower pace, and finally reaches its maximum.

The only flaw which I have found in the treatment is that it will not cure a large proportion of cases of chronic bronchitis *completely;* there frequently remains an occasional cough, with or without a slight *non*-purulent discharge from the tubes. I have not yet found a method of making the cure in all successful cases complete. I should be grateful for any suggestion in this direction. The explanation why a perfect, ideal cure is exceptional is, from a pathologic standpoint, easy to explain. The hypertrophied bronchial mucous membrane will naturally remain hypertrophied, and manifest its condition by some sensitiveness and hypersecretion. My most unsuccessful cases of chronic bronchitis are those which are classified as *catarrhe sec;* on auscultation one hears, or does not hear, an occasional piping râle and harsh breathing, and the patient states that he raises no phlegm. These cases of chronic, dry, hacking bronchial cough, especially in elderly people, I have frequently found disappointing.

If an asthmatic has sufficient control over his respiration during an attack to inhale the spray the paroxysm can be aborted.

During the last two hay-fever seasons patients have regularly come for relief of their dyspnea, after having once tested the method. It is an excellent palliative in these cases.

I believe that the inhalation should be used in pertussis. In the light of newer research concerning the probable localization of the pertussis-infection the spray must also in this disease be forced below the trachea to be of any benefit.

In those cases of nasal asthma, with persistent bronchitis after the nasal treatment has been exhausted, it is a very useful, and frequently curative after-treatment.

To those who are not discouraged with all treatments in pulmonary tuberculosis I would suggest this method for the exhibition of creasote. In a 1 per cent. oily solution creasote is barely perceived; they could therefore use considerably stronger solutions.

In *acute* bronchitis, without fever, the effectiveness of the spray is so pronounced that those who have had experience with it resort to it at each onset of a bronchial disturbance. I am strongly tempted to the claim that it will abort acute bronchitis; but conscious of the liability to fallacious conclusions in a self-limited and naturally brief disease, I make it with all possible caution. If it does not abort every attack, it certainly alleviates all of them.

Do the chronic cases relapse? As I have been employing this treatment for only two years I cannot give a final answer. Those relapses which have come under my notice were discharged after a few treatments.

In chronic cases it is best to begin with daily inhalations for a few days, then on alternate days, then at intermissions of three, four or more days; then once a week will suffice, until a maximum result has been reached. In this manner it is possible to extend a minimal number of treatments over several months, which amount of time is required in the severer cases. I do not, as a rule, exhibit medicines during this treatment, as they are usually superfluous. When there is dyspnea associated with the trouble the potassium iodid should not be dispensed with. Codeine and the wine or syrup of tar seem to rank next in usefulness.

I can afford to prescribe these drugs now without jeopardizing the conclusions drawn from the effectiveness of the inhalation, because by former exclusively topical treatment I have learned how much to attribute to medicinal and how much to the topical treatment. I never use drugs in the beginning of the treatment, in order to get a clear result from the inhalations.

Murrell's publication of 1890 does not seem to have stimulated the profession, if I may judge by the lack of literature on the subject. I have seen no reference to anything like my modification of Murrell's treatment in the foreign and domestic journals at my command, nor do Schmidt's *Jahrbücher,* or Sajous's *Annual* refer to any such treatment.

Beverley Robinson, in his monograph on "Inhalers, Inhalations and Inhalants," in the *Physicians' Leisure Library,* describes the deep sprays with alcoholic and watery menstrua. He has justly deserted these as inefficient, and advocates vapor inhalations with the globe inhaler. This method seems useful, but is far slower and weaker in its result than the method I have described.

ORIGINAL LECTURE.

TALIPES VALGUS AND TALIPES CALCANEUS.

BY DE FOREST WILLARD, M.D.,
CLINICAL PROFESSOR OF ORTHOPEDIC SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

[Reported by DR. JAMES K. YOUNG.]

I HAVE to-day a number of interesting cases upon which I shall operate during the hour: a case of talipes valgus, which requires tenotomy of the tendo Achillis and of the peroneal tendons, together with forcible reduction of the deformity; and three cases of talipes calcaneus, which require shortening of the tendo Achillis. This latter operation is sometimes known as Willet's operation; but I do not like the plan of attaching a man's name to an operation, as it is not expressive and is confusing.

OPERATION FOR TALIPES VALGUS.

The first patient is a girl, ten years of age, who, when an infant, had an attack of infantile paralysis, which has left as a sequela a paralysis only of the muscles of the leg. At the time of the attack, which was accompanied with all of the usual symptoms of acute poliomyelitis, the entire limb was affected; but the condition has gradually regressed, until, as you see, the leg and foot only are involved. The foot is markedly everted, from the tension of the peroneal tendons, and when we attempt to flex the foot upon the leg it cannot be brought to a right angle. This condition is due, in a measure, to paralysis and to elongation of the opposing muscles; but it is also due to the changed relationship that exists between the foot and the leg by the growth of the bones and joints; the soft parts remaining, in consequence of the paralysis, more or less diminished in growth, while the direction in which the body-weight falls upon the foot in its deformed position is abnormal.

In many cases of valgus the error is made in deciding that equinus does not exist simply because the ball and sole of the foot can be brought upon the ground, and the angle of the foot, with the leg, seems to be a right angle. On closer inspection it will frequently be discovered that the tendo Achillis is really much too short, and that the apparently fair position is gained by an elongation of the plantar ligaments, producing a decided false position of the medio-tarsal articulation, and a tendency to flat-foot. Such a condition tends to grow steadily worse, and is only remediable by tenotomy of the tendo Achillis with forcible replacement.

To divide the tendo Achillis, the puncture should be made with a sharp-pointed tenotome, upon the inner side of the tendon, about one inch above its insertion. It is best to slightly retract the skin, so that the puncture of the skin and that of the sheath of the tendon will not correspond. The blunt-pointed tenotome should be inserted flatwise beneath the tendon, and pushed well across; the foot then being flexed strongly, the cutting edge is turned toward the tendon, and by a slight sawing or rocking motion the tendon is severed. As soon as the tendon is divided flexion of the foot is removed, and the tenotome, again turned flatwise, is withdrawn.

In dividing the peroneal tendons it is better to pass the knife between the skin and the tendons and cut directly down on them. This can readily be accomplished by making the puncture and inserting the probe-pointed tenotome just above the tendons, which are brought into prominence behind the external malleolus by strongly everting the foot.

A piece of lint soaked in a 1:1000 solution of mercuric chlorid is applied to the punctures, and secured in position by a dry gauze dressing, antiseptic cotton and antiseptic roller. The foot, after being forcibly reduced into an over-corrected position, is retained by means of a plaster-dressing.

[The parts having been previously prepared by a thorough scrubbing with soap, water, and mercurial solution 1:1000, and the patient etherized, tenotomy of the peroneal tendons and of the tendo Achillis was performed, after which the deformity was over-corrected by manual force. The foot was dressed antiseptically and retained in a plaster-dressing. This dressing will be retained for ten days or two weeks, when it will be removed and a walking-shoe applied. This consists of steel uprights attached to the shoe below, and to a band passing about the leg under the knee, with a joint opposite the ankle, which is so arranged that the foot can be freely flexed, but cannot be extended beyond a right angle. Upon the inner side of the ankle-joint will be placed an oval pad to prevent inversion of the foot. An elastic strap attached opposite the great toe will constantly exert an inverting power upon the foot, while the stirrup will be so adjusted in its relation to the shoe that the tendency will be to throw the foot upon the outer side.]

HELPLESS CRIPPLE—LIMBS USELESS—INFANTILE PARALYSIS.

The next patient is a child of four years, suffering from the effects of infantile paralysis, who has been brought to the clinic from the mountain regions of North Carolina. There is no hereditary history of nervous disease or of deformity. The child is bright and well nourished; but she is not able to walk at all or to creep. When placed upon the floor, she pulls herself along by her arms, dragging her paralyzed legs after her. She can bear her weight upon her left limb when placed upon it, but there is marked back-knee. The right hangs perfectly helpless. We must do all we can to put this little one upon her limbs and enable her to help herself. The first step will be to put her legs and feet into such position, mechanically, that she can use them. Fortunately, she has no contractures higher up than in the calf-muscles, and if the feet are brought into proper shape she can be placed upright upon a supporting apparatus, after which efforts at locomotion will daily bring additional strength to the enfeebled muscles, and in time she will walk with considerable facility. Any improvement will be better than her present helpless condition, even though it be but upon crutches.

I propose to cut the right tendo Achillis and forcibly correct the deformity, retaining the limb in a plaster cast, and, on the left side, to cut and shorten the tendo Achillis, and finally to reduce the varus deformity. The incision should be made vertically down upon the posterior surface of the tendon in such a manner as to secure the greatest exposure, so that the center of the incision shall be over the point of election. The

tendon will be divided about an inch above its insertion. The sheath must be cleanly divided, and the tendon gently removed from its bed by passing a grooved director beneath it. The tendon may then be divided by an oblique incision from above downward and from within outward.

The ends are then secured by hemostatic forceps, the cut surfaces being held in apposition. The ends are slid past each other for three-quarters of an inch, this being the amount of shortening required, and while they are held closely together the two sections are secured by fine chromicized catgut sutures, of which three will be sufficient. The ends that have been pinched must then be cut off, as they may undergo necrosis and prevent union if allowed to remain in the wound The parts must be thoroughly washed with a mercurial solution 1:1000, the incision closed with catgut or silkworm-gut sutures, and the parts protected by a full antiseptic dressing. The foot must be securely held by the hand of an assistant in an extended position until it is firmly fixed in the plaster-of-Paris dressing. The instep, as well as the malleoli and the surface of the wound, will be freely padded with cotton.

In three weeks the patient will be put upon a walking apparatus, which will consist of steel uprights extending from the shoes to a pelvic band about the waist. On the right side there will be a stop-joint, which will allow the foot to flex freely, but not to extend beyond a right angle; while an elastic strap, attached opposite the little toe to the outer upright, will constantly exert traction on the contracted tissue. At the left ankle there will be a stop-joint to allow the foot to extend, but not to flex beyond a right angle. A rubber artificial muscle will be attached to the heel of the shoe and pass to the leg-band below the knee. At the right knee there will be a lock-joint to fix the feeble knee, and on the left side a stop-joint to prevent the limb from being forced backward into a position of back-knee. With these operations, and with the apparatus that has been prescribed, and with massage, we hope to put the child upon her feet and permit her to walk.

TALIPES CALCANEUS AND CAVUS—INFANTILE PARALYSIS.

The next patient is a young woman, twenty-six years old; strong and robust. There is no history of tuberculosis. Her mother is living and well. Her father had paralysis five years before his death, but died of strangulated hernia. She has five brothers and three sisters living and in good health.

Her present trouble began at six years of age, during the summer. She had not been well for a day, and suddenly noticed a paralysis of the left limb. Her present condition shows considerable wasting of the left limb; the left calf measures 11½ inches, and right 14½ inches.

There is paralysis of the tibialis anticus, extensor longus digitorum, peronei, and gastrocnemius muscles, the foot being in a position of marked cavus.

In this case we will shorten the tendo Achillis by the same operation as was performed in the preceding case, but we will divide the tendon by a long longitudinal section, uniting the ends of this incision by a transverse incision passing from the central incision to the border of the tendon, then overlapping these cut ends a sufficient distance to correct the deformity, and suturing the cut surfaces securely together.

[The parts having been previously rendered aseptic, and the patient etherized, the tendon was exposed, as in the previous operation. With a sharp-pointed scalpel the tendon was split for a distance of two inches by a longitudinal incision from behind forward, extending through the entire thickness of the tendon. From the upper part of this incision the inner portion of the tendon was divided by a transverse incision passing inward, and from the lower part of this incision the outer portion of the tendon was divided by another transverse incision passing outward. The cut ends were overlapped for half an inch, and while the cut surfaces were held by forceps attached to the ends of the severed tendon the parts were secured by four chromicized sutures. The bruised ends of the tendon were cut off, the sutures cut short, the wound washed, closed, and dressed antiseptically, the foot being retained in an extended position by a plaster-of-Paris bandage. For the relief of the cavus the plantar fascia was freely divided, and strong force was applied upon the top of the instep to break down the exaggerated arch.]

The dressing will remain for three weeks, and then we will apply a walking-shoe. The shoe will have an insole or shank built in it to give it additional strength, for the attachment of the stirrup of the brace and for a depressing strap to act upon the cavus. The lateral steel uprights extend to just below the knee, and there will be a stop-joint at the ankle to permit full extension, but to limit flexion. Behind, an elastic strap will check flexion and tend to constantly extend the foot upon the leg, thus relieving the shortened tendon for a time until it has fully recovered. On the outer and inner ankle-joints there will be small rounds pads to maintain the foot in good position. With this apparatus the woman's condition, and appearance also, will be much improved.

INFANTILE PARALYSIS—TALIPES CALCANEO-VALGUS.

The next case is in a boy, nine years old, who has always been strong and hearty, and has never had any illness, except a mild attack of scarlatina. Both parents are living and well. The family history is negative.

The present deformity began at about one year of age before the boy began to walk. Of late it has grown rapidly worse.

On examination there is observed almost a posterior displacement of the astragalus, with great eversion of the sole of the foot. He walks more and more upon the scaphoid and upon the calcaneum. To permit of this there is a marked lengthening of the tendo Achillis. The foot is held in this everted position by the tension of the peroneal tendons, which, as the foot is inverted, are brought prominently into view. The tendo Achillis will be cut across obliquely and shortened one-third of an inch, and securely sutured with chromicized sutures, and the peroneal tendons will be divided through the same wound. There are no important vessels here, and the tenotome can be carried outward; this will avoid making an additional puncture. The foot will be dressed in the extended position, as in the preceding cases.

[The parts having been previously prepared, and the

patient etherized, the tendon was shortened in the same manner as in the second case. The wound was then washed with mercurial solution; the skin-wound was closed by means of interrupted catgut sutures, and the wound was dressed with aristol powder and covered with a full antiseptic dressing. The foot was then held in an inverted and extended position and fixed in a plaster-of-Paris dressing.]

After three weeks a walking-apparatus will be applied, similar to the one in the last case. To maintain the foot in its corrected position a pad will be placed opposite the inner ankle, and the shoe will be attached to the stirrup, so as to slope outward and to throw the foot upon its outer plantar surface, while an elastic strip fixed opposite to the great toe will continually lift the inner portion of the foot.

MEDICAL PROGRESS.

Two Symphysiotomies, one for the Extraction of a Decapitated and Imprisoned Head.—SCHWARZ (*Centralbl. f. Gynäkol.*, 1893, No. 5, p. 84) has reported the case of a tertipara, twenty-two years old, whose first child was delivered, dead, by means of forceps; the second child was also born still, version having been necessary. In the third labor version was practised in the hope of expediting a tardy delivery, but the head could not be born, either spontaneously by the contractions of the uterus or with the aid of forceps. Decapitation was performed, but the uterus became tetanically contracted and the head could not be removed. Considerable hemorrhage occurred from a wound in the lower segment of the uterus. As a further complication, an eclamptic attack took place. The pelvis was generally contracted. After the lapse of a considerable time symphysiotomy was decided upon. As soon as the section had been made the head, which was disproportionately large, was readily delivered by means of forceps. Three hours after the operation a second eclamptic attack occurred. During the puerperium the temperature was elevated; there was considerable offensive discharge; and the urine contained a small quantity of albumin. The wound had healed at the end of eight days. At the end of six weeks the woman was out of bed; at the end of eight weeks she could walk firmly.

The second case was in a woman, twenty-two years old, with a rhachitic pelvis. The child occupied a transverse position; the left arm had prolapsed; the uterus was tetanically contracted. Version was attempted, but could not be accomplished because of the prominence and depression of the sacral promonotory. Symphysiotomy was determined upon. The articular cartilage was found ossified, and a saw had to be employed in its division. The child had meanwhile died. In the mother parametritis and pelvic peritonitis developed, and she died on the eighth day of general peritonitis. After death it was found that the uterus was not profoundly involved, but that the fatal process had had its origin in a cellulitis consequent upon the difficulties and traumatisms of the operation.

Extirpation of the Gall-bladder.—At a meeting of the Medical Society of Greifswald, HELFERICH (*Deutsche medicin. Wochenschr.*, 1892, No. 45, p. 1020) presented a man, forty-two years old, whose gall-bladder had been extirpated. For three months there had been gastric derangement without jaundice. In the abdomen a tumor was detected corresponding in form, size, situation, and relations with the gall-bladder, and slightly movable with change in position. From the fact that the tumor could be made to disappear by distending the rectum with air, and from the pain induced by examination, it was concluded that there were numerous adhesions, and that the contents of the bladder were purulent. The abdomen was opened by an incision along the outer margin of the right rectus muscle, which was joined by another incision at right angles and directed toward the middle line. After the adhesions were broken up and precautions against contamination of the wound and the peritoneum were taken, the gall-bladder was opened and about half a pint of pus was evacuated, with some oil-globules and débris of calculi. A calculus almost as large as a cherry, wedged in the cystic duct, was removed with some difficulty. On account of the presence of pus and of the probability of ulceration of the cystic duct, and of marked changes in the walls of the gall-bladder, it was decided to perform cholecystectomy. The cystic duct was divided at a healthy point and its lumen closed by a Lembert suture. The bladder was then easily removed. The wound was carefully approximated, and no drainage was provided for. The subsequent course of the case was entirely afebrile. The patient made a speedy and perfect recovery.

Intra thoracic Goiter.—WIESMANN (*Corr.-bl. f. Schweizer Aerzte*, 1893, 1, p. 23) has reported the case of a man, fifty-six years old, of whom it could only be learned that he had suffered from dyspnea during his whole life. The head and the upper part of the body were bent forward. Breathing was stertorous and attended with the bruit of respiratory stenosis. The neck was extremely short. To the right of the larynx, but apparently not related to the dyspnea, was a hard nodule as large as a walnut. Heart and lungs presented no abnormality; but an area of dulness on percussion, extending, on either side of the sternum, from the clavicles to the level of the cardiac dulness, was demonstrable. The acute symptoms were relieved by the administration of large doses of potassium iodid and the application of an ice-bag to the chest. Subsequently, dysphagia was added to the clinical picture and the patient soon afterward died, exhausted. At the post-mortem examination, the anterior mediastinum was found occupied by an ovoid mass as large as two fists, extending from the level of the clavicles to that of the bifurcation of the trachea, upon which and upon the pericardium as well, the mass rested. The tumor was a partly cystic goiter. The mass to the right of the larynx proved to be a calcareous thyroid gland, which had no apparent parenchymatous connection with the intrathoracic goiter. The trachea was flattened and displaced upon the lateral aspect of the tumor to the right. The esophagus traversed the posterior aspect of the mass; it had also suffered some lateral displacement; its upper portion presented a diverticulum.

Two Rare Tumors of the Thigh.—BOEGEL (*Centralbl. f. Chirurgie*, 1892, No. 48, p. 1007) has reported the case

of a man, forty-three years old, who for two years had observed a progressive swelling upon the posterior aspect of the left thigh, with which for several months had been associated local pain, at times extending to the sole of the foot, and alternating with formication. On operation, a large, dense, ovoid tumor was found, occupying quite the lower half of the posterior aspect of the thigh, and separating the heads of the biceps and semi-tendinous muscles. The growth was connected with the sciatic nerve, the fibers of which coursed along its anterior surface. On microscopic examination the tumor was found to present the histologic appearances of a lymphangiectatic fibro-sarcoma. In the same person a second tumor, which proved to be a large lipoma, was removed from the upper part of the corresponding thigh. The mass was situated externally to the long head of the biceps, and was attached by its capsule to the tuber ischii. The man recovered without any unpleasant sequelæ. The second case was in a woman, thirty-five years old, who had accidentally discovered a tumor upon the posterior surface of the left thigh, which occasioned no special discomfort, but grew rapidly. The tumor was found to be as large as a child's head, and was attached to the fascia of the semi-tendinous muscle. On microscopic examination it proved to be a lymphangiectatic fibro-myxoma.

A Case Symphysiotomy.—KRASSOWSKY (*Centralbl. f. Gynäkologie*, 1893, No. 5, p. 81) has reported the case of a deutipara, twenty-three years old, with a contracted pelvis (the true conjugate meausuring 2.9 inches) and in labor at term. As the head remained movable above the pelvic inlet and failed to engage, and as in the first labor it had been necessary to practise craniotomy, it was now decided to perform symphysiotomy. The operation was attended with considerable hemorrhage from the cavernous body of the clitoris. During the application of the forceps the innominate bones separated for a distance of two and a half inches, and the right sacro-iliac articulation was heard to rupture. The child, a girl, weighed six and three-quarter pounds; the greater transverse diameter of the head measured 3.65 inches. The placenta followed the child in fifteen minutes. The puerperium was complicated by cystitis, a little febrile reaction, and some mental excitement. The patient sat up in the third week. On the twentieth day she stood up, but on account of weakness could walk but a few steps. A day later she was able to do better, although the gait was a little unsteady. There was slight mobility at the symphysis.

THERAPEUTIC NOTES.

Teucrin—A New Therapeutic Agent.—MOSETIG (*Internationale klin. Rundschau*, vii, 6, p. 214) has prepared from the plant teucrium scordium an extract to which he gives the name teucrin and that he has successfully employed by subcutaneous injection in the treatment of various mycotic affections. An infusion is prepared by means of hot distilled water from the dried and not too old plant; the expressed fluid is concentrated to the consistency of honey, repeatedly cleared with alcohol, finally evaporated to a specific gravity of 1.15 and introduced into sterilized vials which are hermetically sealed. The product is a dark-brown fluid, with a pungent, bitter taste, and miscible in all proportions with water. The dose is forty-five minims injected subcutaneously. The agent has been employed most largely in the treatment of tuberculosis of soft tissues. The injection is followed by constitutional symptoms that last perhaps for eight or ten hours. In from half an hour to four hours the temperature rises; occasionally there is a chill; in a few cases cutaneous eruptions appeared; in cases in which pulmonary tuberculosis also existed the sputum assumed a milky appearance. Breaking down took place at the site of local disease, with a throwing off or absorption of the disintegrated structures.

Hiccough Relieved by the Wet-pack.—CHAMBARD-HENON (*Rev. de Thér. méd.-chir.*, 1893, No. 3, p. 77) has reported the case of a man, thirty-four years old, in which, in the third week of an attack of scarlatina, incessant hiccough appeared, preventing sleep and interfering with the taking of food and drink. The urine was scanty, high-colored, but contained no albumin. The temperature ranged between 101° and 102°. After all other measures had been exhausted, it was concluded to apply peripheral stimulation, in the hope of overcoming spasm and establishing diuresis. Accordingly, the man was every three hours placed for five minutes in a wet-pack. After the third application the flow of urine increased and the hiccough subsided. In all, twenty-nine applications were made and the relief was permanent. The view is expressed that the hiccough was dependent upon an action upon the nervous system by the toxins of scarlatina, upon the elimination of which with the urine the symptoms disappeared.

Peculiar Toxic Symptoms from Antipyrin.—FREUDENBERG (*Centralb. f. klin. Medicin*, 1893, No. 5, p. 97) has reported the case of a man, thirty years old, in which following the ingestion of a single dose of seven and a half grains of antipyrin, a sense of burning in the urethra was perceived, and from which on pressure a drop of clear, thin fluid could be expressed. There was at the same time intense itching of the prepuce and scrotum, while the prepuce was swollen from edema. The urine was clear and contained no albumin. To confirm the accuracy of the observation the man was, at a later period, given a similar dose of antipyrin. Within an hour and a half itching appeared, and in five hours and a half prepuce and scrotum were swollen. No other parts of the body were affected, except perhaps the lower lip, which became somewhat reddened and swollen.

THE WHITE BLOOD-CORPUSCLES.

As early as 1845 VIRCHOW had noticed that in the leukocytosis attending certain diseases the small white corpuscles predominated, while in others the large forms prevailed, and he was able thus to divide leukemia into two varieties. Twenty years or more later the histologic characters of the blood were studied by MAX SCHULTZE, and his observation that the white cells of the blood presented "no morphologic unity" stimulated many to the closer study of them. Foremost among the investigators of the blood has been EHRLICH, of Berlin, and his happy application of the method of KOCH of preparing cover-glass specimens, by means of which the blood is studied in dried and stained preparations, has led to a vast widening of our knowledge of hemopathology.

EHRLICH'S descriptions of the "specific granulations" of the leukocytes, and his methods of differentiating them by micro-chemical reactions, are now so well known and readily accessible that we shall do no more than make passing reference to them here. It will be remembered that, according to EHRLICH, there are in normal blood five varieties of white corpuscles: 1. Lymphocytes, small elements the nuclei of which stain intensely in the triple stain, and about which there is only a small rim of protoplasmic substance. These cells are believed by EHRLICH to have their origin in the lymph-glands and lymphatic tissue of the body generally. 2. Large mononuclear elements, cells which contain a large oval or ovoid, feebly staining nucleus which is usually placed excentrically in the cell, the protoplasm being relatively well developed. 3. Leukocytes, with polymorphous nuclei, or the so-called "polynuclear leukocytes." These are larger than the lymphocytes, and smaller than the large mononuclear elements, and are characterized by the presence of S-, V-, Y-, Z-, or E-shaped nuclei, the protoplasm being thickly studded with fine granules, which stain intensely in neutral coloring mixtures, the ϵ-granulation, or neutrophilic granulation. 4. Transition forms between forms 2 and 3, in which the nucleus shows indentations and the protoplasm often a few neutrophilic granules. 5. Eosinophiles, cells varying in size and in the appearance of their nuclei, and the protoplasm of which contains large globular granules, which have a particular affinity for the acid dyes, and more especially for eosin.

In health these varieties are generally found to be present in fairly constant proportions, the lymphocytes forming from 15 to 30 per cent., the polynuclear neutrophiles from 60 to 75 per cent., the mononuclear and transition forms 6 per cent., and the eosinophiles from 2 to 4 per cent. of the whole number of the white corpuscles.

The determination of deviations from this normal relationship gives much more valuable information than a simple numerical estimate of the total number of all leukocytes present. Thus, in the acute exudative inflammations, accompanied by leukocytosis, the increase is chiefly in the polynuclear neutrophiles—not a matter of surprise when we recollect that these cells are the only ones known positively to leave the vessels in inflammation. It has been claimed that the polynuclear leukocyte owes its emigrative power to the high degree of ameboid movement which it possesses, but this is a point not yet settled. KANTHACK has only recently claimed to have demonstrated in experimental inflammations the emigration of small mononuclear leukocytes, but his observations, together with such theories as that of HANKIN, who believes that the defensive proteids of the blood-serum have their origin in certain of the leukocytic granulations, cannot be held to have been satisfactorily proved until a

sufficient number of control-investigations have confirmed them.

While the modern clinician appreciates the value of EHRLICH'S methods in the study of the diseases of the blood proper, and would not neglect to make use of them when dealing with a case of grave anemia or of leukemia, we fear that the importance of systematic blood-examinations in the ordinary infections and cachexias has heretofore been insufficiently recognized. To take a single example, it has long been known that in uncomplicated cases of typhoid fever there is in the blood no evidence of leukocytosis—that, indeed, the number of white corpuscles may go below the normal. But the differential count in stained specimens shows a marked alteration in the numbers of the individual varieties present, the large mononuclear elements being relatively increased, and the neutrophiles, with polymorphous nuclei, relatively diminished, while the number of lymphocytes remains essentially normal.

The appearance of a leukocytosis, or of a relative increase in the neutrophiles, would then in typhoid fever be strongly suggestive of an acute complicating inflammation elsewhere in the body—perhaps, for instance, in the lung or in the pleura. When, therefore, the physical signs are obscure, the color-analysis of the leukocytes might aid materially in the differential diagnosis.

But our special object in this article is to draw attention to a classification of the leukocytes more minute even than that of EHRLICH, although it is based upon and has been worked out by the methods employed by him. USKOW, of St. Petersburg, in 1890, in a monograph entitled *The Blood as a Tissue*, has studied the colorless corpuscles by means of contrast-stains with the greatest care and minuteness. His article appeared in the Russian language and so has been practically inaccessible to the majority of readers. A short reference to it appeared, indeed, in *Virchow's Archives*, but was so incomplete as to be of little service. We are pleased to find, in a lecture delivered by THAYER[1] before a section of the Massachusetts Medical Society, a complete account of USKOW'S investigations. The leukocytes are divided into: (1) Small lymphocytes, cells the size of a red corpuscle or smaller; (2) large lymphocytes in which the protoplasmic ring about the nucleus is a little larger and more irregular; (3) small, transparent corpuscles, cells about the size of the large lymphocytes, the nuclei of which stain more or less feebly, the protoplasm taking on no stain whatever; (4) large, transparent corpuscles, cells from three to five times the size of red corpuscles, in which the protoplasm takes on no stain; (5) giant, transparent corpuscles—the largest elements seen in the blood. Besides these there are corpuscles similar in size to these transparent forms, in which the protoplasm stains feebly, standing midway between that of the lymphocytes and that of the transparent corpuscles in its affinity for coloring matters. USKOW, therefore, includes in his classification: (6) Small transitional forms or giant lymphocytes; (7) large transitional forms, and (8) giant transitional forms. Finally, there are (9) the "multinuclear" neutrophilic leukocytes, of which he mentions three varieties, and (10) the eosinophilic leukocytes. USKOW concludes further from his experimental work on animals that the white corpuscles may be divided into (*a*) *young* elements, (*b*) *ripe* elements, and (*c*) *over-ripe* elements. Among the young elements he places the small transparent leukocytes, and the small and large lymphocytes; among the ripe forms, the small, large, and giant transitional leukocytes, and the large and giant transparent elements; the multinuclear neutrophiles and eosinophilic leukocytes are regarded as over-ripe forms, as they can be traced through various degenerative stages to their final dissolution.

Anyone who will take the trouble to examine his blood-slides stained with the EHRLICH-BIONDI mixture will easily convince himself of the accuracy of USKOW'S classification. However, as THAYER points out, in making differential counts in ordinary work, the adoption of this classification will lead to some difficulty, as the lines drawn between some of the forms will vary with different observers. To overcome this, certain modifications have been suggested by TSCHISTOWITCH and others. But for these we must refer our readers to THAYER'S article, in which will be found not only a careful account of technical methods, but also an interesting *résumé* of the most valuable of the recent contributions to our knowledge of the histologic characters of the blood in disease, including many interesting personal observations.

The Consumption of Alcohol in France was, in 1850, one liter sixty centiliters for each person; in 1870 the corresponding figures were two liters eighty-one centiliters; in 1885, three liters eighty-five centiliters.

EDITORIAL COMMENTS.

Deaths from Poisoning in England and Wales.—The *British Medical Journal*, January 28, 1893, p. 191, publishes an interesting summary of the cases of poisoning that occurred in England and Wales during the year 1891, based upon data contained in the annual report of the Registrar-General. The total number of deaths from poisoning during the year was 876, being 242 more than in 1889. Of this number, 544 cases were accidental, 327 were cases of suicide, and 5 were cases of homicide. Among those in the first group, 132 deaths were due to lead-poisoning; and 114 to narcotic poisoning by "opium, laudanum, morphine, chlorodyne, soothing syrup, paregoric." In 62 cases of accidental poisoning death was due to chloroform; in 31 to carbolic acid; in 19 to the poisonous alkaloids; in 17 to the mineral acids; in 8 to arsenic; in 7 to chloral; in 2 to oxalic acid. In 128 cases death was due to miscellaneous poisons. In 24 cases the nature of the poison was not clear. Among the cases of suicide, death was due to "opium, laudanum, morphine, chlorodyne, in 56 cases (17.1 per cent.)"; to carbolic acid in 63 (19 per cent.); to mineral acids in 28; to arsenic in but 6; to hydrocyanic acid or potassium cyanid in 36; to one or other of the potent alkaloids in 27 instances; to oxalic acid in 20 cases. Of the suicides, 178 were males and 149 females. Relatively to the total number of suicides by either sex, poison was much more frequently had recourse to by females. Taking both sexes together, death resulted from poisoning in one-eighth of the total number of suicides. Among the deaths by accident from all causes, poisoning figures in rather less than one-thirtieth, and twice as frequently among males as among females. Legislation cannot be too stringent in controlling the sale of recognized poisons and of substanes or medicines of which the composition is unknown.

Black Tongue is the descriptive name given to a condition characterized by the formation upon the dorsum of the tongue of a hair-like deposit that passes through various stages of coloration from yellow to brown and finally black, ultimately disappearing by desquamation as gradually as it came. Repeated recurrence is the rule. The manifestation is not known to be associated with any definite derangement of the general condition. The process is thought to be a result of irritation, resulting in undue proliferation of the epithelium, particularly of the filiform papillæ. The affection is rather a rare one, though, by a coincidence, we have seen half a dozen instances in the course of a year. In all of these the teeth presented a deposit of dense black pigment, such as is not uncommon in those that are negligent in the care of the teeth. A good description of the condition will be found in the *Transactions of the Pathological Society of Philadelphia*, vol. xiii, p. 70.[1] Morelli (*Compt. rend. hebdom. des Séances de la Soc. de Biologie*, s. 9, t. v, No. 1, p. 23), reports a case, with the results of a bacteriologic study. In a scraping from the tongue, among and within some of the epithelial cells, and by cultivation in artificial media, he succeeded in finding a bacillus, from 0 3 to 0.4 μ thick and from 2 to 4 μ long. Spores could not be demonstrated; nor could the condition be reproduced by inoculation. Attention is called to the fact that black tongue is habitual in parrots and in giraffes, and is occasionally present in cows and in goats. Morelli was unable, however, to demonstrate in the case of parrots the presence of a microbe corresponding with that found in the case of man.

[1] S. S. Cohen: Two Specimens of Melanotic Hypertrophy of the Filiform Papillæ of the Tongue (Black Tongue).

The Microbe of Beri-beri.—Beri-beri, or kak-ké, is practically unknown in this country, unless it be admitted that the cases recorded several years ago by J. J. Putnam[1] among some fishermen on the New England coast were instances of the affection. The disease is, however, at home in China, Japan, the East Indies, and Brazil, where it is endemic and occasionally epidemic. It appears in one of two forms, presenting either the symptoms of an acute infection, with febrile manifestations, anasarca, anemia, and frequently death, or more especially those of multiple neuritis, with motor, sensory, and trophic phenomena. As indicated, the clinical picture is suggestive of an infectious process, and biologic studies appear to have confirmed the accuracy of this assumption. Musso and Morelli (*Compt. rend. hebdom. des Séances de la Soc. de Biologie*, s. 9, t. v, No. 1, p. 18) report having succeeded in isolating by culture from the blood, the fluid effused into the serous cavities and subcutaneous tissues, the peripheral nerves, and the medulla in a number of cases of beri-beri in Brazil, micrococci that they believe to be identical with those already described by Lacerda, Ogata, and Eykmann as the specific cause of the disease. Inoculations of the organism were fatal to rabbits and guinea-pigs; dogs were more refractory. In the former apathy and paresis of the posterior extremities appeared, followed after a varying interval by death. After death, effusions into the serous cavities were found, together with the evidences of neuritis and the presence of organisms identical with those inoculated.

Diabetes of Pancreatic Origin.—Of the diseases of the pancreas even less is known than of its function. Recent investigations tend to show that in addition to its amylolytic, its proteolytic, and its fat-converting functions the pancreas possesses a glycolytic function. It had already been observed that in some cases of diabetes mellitus the pancreas presented degenerative changes, but it remained for recent investigators to establish incontrovertibly the relation between the disease of the gland and the clinical manifestations. It has been shown experimentally (and the evidence has been confirmed by clinical observation) that total destruction of the pancreas is essential for the development of this particular variety of diabetes—for it is well known that diabetes may also be caused by a lesion in the floor of the fourth ventricle.

Freyhan (*Berliner klin. Wochenschr.*, xxx, 6, p. 129) has reported two cases of diabetes in which, after death, the pancreatic duct was found to be occluded by calculi, while the gland itself was entirely disorganized and replaced by fibrous and fatty tissue.

To thus recognize that diabetes mellitus may be of diverse origin is in itself a distinct advance.

[1] Cited by Osler: Practice of Medicine, p. 780.

What therapeutic fruit this new knowledge will bear it is yet too early to realize. The administration of prepared pancreas to diabetics has thus far not been attended with especially encouraging results.

A New Preparation of the Thyroid Gland for the Treatment of Myxedema.—The remarkable results obtained in the treatment of myxedema by means of preparations of the thyroid gland have stimulated investigators to find some method of preparing a dry, stable preparation to replace the crude gland or the extracts that have been employed. Guided by a belief that the thyroid gland might contain some hitherto undescribed ferment White (*British Medical Journal*, No. 1676, p. 289) determined to try whether, by the formation of gelatinous or flocculent precipitates in liquid extracts known to possess the desired activity, the active principle could be separated from the large amount of proteid and other organic substances present. The glands were first exhausted with a mixture of equal parts of glycerin and water. The filtered fluid was acidulated with phosphoric acid, and calcium hydrate was added until an alkaline reaction was produced. The precipitate was filtered out as rapidly as possible, washed and dried over sulphuric acid without heat. Of the resulting powder the dose is three grains. Good results have attended its use.

The Woman's Medical Journal, "a monthly journal devoted to the interests of women physicians," is the name of the latest venture in medical journalism. This apparent exclusiveness of purpose is somewhat relaxed by an editorial assurance that the journal "will print news and notes of interest to the masculine as well as the feminine part of the profession." We had heretofore not been aware that women in medicine had professional interests apart from those common to all physicians. Surely woman in medicine has received fair and generous treatment and has proved herself abundantly capable to take care of herself without the necessity of special protection. The real *motif* of the venture may, however, be concealed in the concluding words of the salutatory, which "expresses appreciation of the advertisers who appear in our advertising pages, and trust that each reader will see something which she desires, and send for it at once."

Gynecology Among the Insane.—With a reckless haste and publicity not altogether above suspicion of some unworthy political influence, the Pennsylvania State Board of Public Charities condemned the use of surgical methods of relief among the inmates of the female department of the State Asylum at Norristown. The public has thus become more certain than ever of the justice of its horror of the imagined abuses practised by the profession upon the defenceless insane and sick. The Board of Trustees of the Asylum, and Dr. Bennett, in reply to the State Board of Charities, have more than met all the charges, and have clearly shown that the question of sanity or insanity has not been considered in the removal of the diseased organs of the six cases complained of. If nothing else is immortal, the bitter suspicion and deep-seated grudge against the medical profession seems destined never to die.

The New Immigration Law enacted last week and signed by President Harrison underwent the usual crippling process in order that some law on the subject might be passed and that some restriction might be made obligatory. Masters of vessels and surgeons at the sailing ports are required to make affidavit before our consuls as to the emigrant's condition, physical, educational, fiscal, moral, etc., as to his purposes, destination, and whether his passage has been paid for him or not. Upon arrival at our ports special inquiry shall again be instituted by the U. S. officials as to the immigrant's fitness to land. While all these provisions are excellent, they are not so thorough-going as the circumstances would seem to warrant. The power of the local inspectors of immigration is, as it should be, curtailed and the General Government assumes control of the matter.

Regulations at Foreign Ports to Prevent Cholera—Surgeon-General Wyman has issued regulations to prevent the emigration from foreign ports of those infected with cholera or other epidemic disease. Cabin passengers must show proof of their places of residence for four days prior to their embarcation, and if they have been exposed to contagious disease they will be detained, their baggage disinfected, etc. Steerage passengers from an infected port are to be detained five days under medical observation, with disinfection, regulations as to cleanliness, etc. If cholera breaks out among them, all are detained until seven days after the last case has recovered.

The Right to Establish Hospitals for Infectious Diseases.—The British Court of Appeals has decided that a local authority has no power to forbid the erection of a hospital within its district by another local authority, whether the hospital be for infectious diseases or not. The city of Manchester thus has power to establish a small-pox hospital on ground it owns in the adjacent town of Withington, despite the opposition of the people of Withington.

The Samuel D. Gross Monument Fund.—The amounts so far subscribed aggregate nearly ten thousand dollars, of which about five thousand have been secured in Philadelphia. Four thousand dollars are still needed to complete the desired amount. Dr. J. B. Chapin is chairman and treasurer of the committee, to whom subscriptions may be forwarded, or to Mr. George Keil, 1715 Willington Sreet, Philadelphia.

Norse Mythology and Cod-liver Oil.—Many of our readers will doubtless have received, and wondered as they read, what possible connection a treatise on *Norse Mythology, the Religion of our Forefathers*, by an LL.D., can have with cod-liver oil. The two subjects are brought together in a strange and illogical copartnership in a pamphlet before us, most noteworthy as a literary and advertising curiosity.

It Does Not Often Happen, because patients are not often so generous, nor practioners so scrupulous, that a physician returns a check for $500 voluntarily tendered, on the ground that the medical service rendered had not been worth so much money. This incident, pleasant to chronicle, happened last week in Philadelphia.

CORRESPONDENCE.

THE PHYSICIAN AND THE PHARMACIST.

To the Editor of THE MEDICAL NEWS,

SIR: In an editorial in a late issue of THE MEDICAL NEWS (February 18, 1893, p. 194), it is said that "the study of pharmacy does not include all the knowledge necessary for the practice of medicine, but the study of medicine does include all the knowledge necessary for the practice of pharmacy, in so far as the protection of the public against danger of mistake is concerned." While holding the opinions of THE MEDICAL NEWS in the greatest respect, yet I feel that they are sometimes wrong, especially when touching upon the subject of pharmacy, and from the views quoted I most positively dissent. Can you sincerely say that you believe a medical graduate, without other training, to be a competent prescriptionist? Would you risk your prescriptions in the hands of such a man? Is there also no other element than danger of mistake to be considered? What of the identity of the various drugs and chemicals that appear upon the market—the ability to distinguish medicinal plants and parts of plants and their products from each other, and from sophistication and impurities, and the best methods of combining leading remedies?

The province of the pharmacist is to preserve drugs that they retain their peculiar properties; to prepare them for use in the best possible manner, as well as to dispense them. This cannot be taught in a few hours. If you will look into the subject you will find that our medical colleges devote to the study of pharmacy from naught to forty-six hours' time of the entire term necessary to the degree. The largest number of hours that I can find is 46; another is 23, another 10, and the announcements of other colleges do not mention pharmacy at all. This, against the 1500 hours of the New York and Philadelphia colleges of pharmacy, and about that amount in the colleges of other cities.

Do you not look upon medicine as a tool with which you are to work—the medium by which you are to produce certain physiologic effects? When you prescribe strychnine you want the physiologic effect of strychnine; you want this as well as to guard against the danger of mistake. If the medical graduate desires to place himself before the public as competent to prepare and dispense medicines, why should he not prove to the public his abilities to do so by a certificate from an examining board? If a pharmacist, who has had at least four years' apprenticeship in pharmacy, who has attended two full courses of lectures and passed an examination in these branches, must appear before such a board, why should not the medical graduate, who has received but a few hours' instruction?

Again, I venture to say that if our physicians received a preparatory course at a college of pharmacy—were this encouraged by our medical colleges rather than to be discouraged, as it is to-day—there would be far greater ability in the profession in the treatment of disease. The subject is distinctive—medical colleges cannot handle it. It is a specialty, and even more of a specialty to medicine than dentistry is to surgery. To say the least, proprietary articles would receive a great blow, for their greatest indorsement to-day is by physicians. A very bright practitioner—a graduate of one of our best universities—recently told me that he had seen but once a copy of the Pharmacopeia and never a National Formulary. He was astonished to learn that lactopeptine was a proprietary article. I would really like to know how many active physicians in the land possess a copy of the last Pharmacopeia. A very small proportion, I imagine; and that number, no doubt, had a previous pharmaceutical training, and can appreciate the value of the U. S. P.

A pharmacist who makes an effort to be truly and legitimately a pharmacist; who makes and prides himself upon fine pharmacopeial preparations, cannot live by his knowledge and labor, because physicians do not support him. He must devote a large portion of his prescription department to opened bottles of So-and-so's elixir, or other quack preparations prescribed by the profession.

Respectfully yours,

M. S. SIMPSON, M.D.

PLAINFIELD, N. J.

[Our esteemed correspondent is both right and wrong. He is right in maintaining that greater attention should be paid to practical pharmacy in medical education; but he is wrong in assuming that the number of hours devoted to this at college represents the entire knowledge and experience of even a large minority of physicians. He is right in condemning the sale of nostrums by druggists and the use of nostrums by physicians; but he is wrong in assuming that physicians in general use nostrums or approve of their sale. THE MEDICAL NEWS has expressed itself fully on this question. The one reason why pharmacists cannot subsist on prescription business alone, and hence believe themselves forced to sell nostrums is that there are more stores in a given neighborhood than necessity demands. The medical profession does cordially support every man who tries to do legitimate pharmacy only. At least one notable example is to be found in Philadelphia. Few druggists nowadays prepare the galenical preparations they dispense, and still fewer adhere to the U. S. P. as closely as they should. We know of more than one instance in which a prescription for an infusion has been filled by diluting with water a purchased fluid extract. We believe that a physician practising pharmacy would be more scrupulous as to the efficiency and purity of his stock than are many pharmacists. He would also be less likely to do "counter-prescribing," for he would realize its dangers more keenly. Further, we hold—and this is the only point of real moment—that the sole justification for restrictive legislation must be that it is necessary for the public safety. On that broad ground we can uphold the present law of Pennsylvania concerning the practice of pharmacy; but we cannot approve of the proposition to repeal Section 11.—ED. NEWS.]

EPILEPSY OR ANGINA PECTORIS?

To the Editor of THE MEDICAL NEWS,

SIR: On the night of August 1, 1892, a man was roused from sleep by a "killing" pain in the region of the heart. There was also dyspnea, so marked as to make utterance difficult, and the heart's action was peculiar in that it was first very rapid and then very slow—so slow, indeed, that the man feared it would soon

stop. The seizure lasted longer than an hour. There was no loss of consciousness. The tongue or lips were not bitten; no frothing was observed. The man did not fall or cry. The pain was limited to an area of twelve inches in diameter, having the heart for its center. Relief was sought in posture, in heat, in opium; but found in none.

The seizure, as described, was repeated every night from August 1st to December 16th, and at the same hour, viz., from 12.30 to 1.30, unless the man remained awake, out of bed. In the morning he insisted that he was as well as ever. During the day no alteration of the respiratory sounds was found, and the heart gave no indication of any fault of structure or function. The man could run or mount stairs without exciting dyspnea and without increasing the rapidity of the heart's action except in a slight degree.

There is no recollection of any injury to the head; no history of specific infection or inheritance. The man is a large, strong, ruddy-faced farmer of thirty-five, and, so far as he knows, no near relative is or has been the subject of chorea, epilepsy, or obstinate neuralgia.

Great apprehension was felt during the first weeks of the invasion—apprehension of immediate death; but time allayed this concern, after prolonged experience, though it did nothing to assuage the severity of the pain.

I am unable to learn what measures were employed by his medical advisers for his relief, but am informed that all were ineffectual; that no interruption or relief of the paroxysm was accomplished.

Consideration of the case compelled the belief that the affection was essentially a neurosis. The regular recurrence, the lack of evidence of the existence of any structural lesion in the interval between attacks, were suggestive of the group of cases described so well by Trousseau as instances of epileptiform neuralgia, though there was in this patient's manner nothing indicative of the nervous organization that ordinarily manifests itself by quick replies, alertness of movement, the mastery of the emotions, and a certain grotesqueness of behavior that is easy to discern but difficult to describe. He was, on the contrary, self-possessed, unimaginative, and had himself in good control, and was rather stolid and impassive. It ought to be added that prior to this seizure, on August 1st, he never experienced any convulsive movement, never had a moment's loss of consciousness, except during sleep, never had even an attack of migraine.

The treatment seems to me to settle any doubt as to the character of the affection. The bromides, in heavy doses, mainly at bedtime, interrupted the paroxysms, and to this date there has been no indication of their return. It should be added that the duration of the paroxysms was not infrequently prolonged to three hours, and was never less than an hour, and that the distress was extreme. The pain was sometimes declared to be greater in the epigastrium, again in the precordium, and again under the clavicles. Tingling and numbness in the arms and a sense of suffocation were described as severe, but no râles or rhonchi were heard during or after the paroxysm. There was no tendency to stupor or drowsiness upon the cessation of the seizure. The statement relating to the dyspnea may suggest a kinship with paroxysmal asthma, idiopathic asthma, but the kinship was no nearer to asthma than to angina, and measures employed against it by the family, such as stramonium, were of no avail; nor does exposure to dust, or, indeed, to any irritant, excite asthmatic attacks. He never had an attack of asthma in his life, unless these seizures were asthmatic. The most notable feature of this case, and one which marks it as anomalous, was its recurrence at a fixed hour, and the fact that it was averted by vigilance. It may be urged that this seems farcical; that a successful attempt to delude has been accomplished by the player-patient. It is scarcely necessary to say that the play was a long and expensive one, and that the cost and suffering were in one person and in one purse.

Respectfully,

J. N. RANDALL, M.D.

DECATUR, ILL., January 26, 1893.

PHYSICIANS AS PHARMACISTS.

To the Editor of THE MEDICAL NEWS,

SIR: In reference to your editorial comment in THE MEDICAL NEWS of February 18th, I feel that I must protest when you say that "The study of medicine does include all the knowledge necessary for the practice of pharmacy, in so far as the protection of the public against danger of mistake is concerned." There are many reasons why your statement is based on unsound reasoning. I will mention but two of them.

1. The physician studies only the remedies which he expects to use in his practice. Few physicians will study or prescribe over one hundred different remedies in a lifetime. The pharmacist's prescription-file will verify this assertion.

The pharmacist must compound and sell hundreds, if not thousands of remedies. His study must include the medicines employed by the regular, eclectic, or homeopathic practitioner, herb doctor, midwife, etc., as well as all domestic remedies. How many physicians have even heard of all the remedies in the Pharmacopeia, much less those of the National Formulary and other pharmaceutical works.

2. The physician does not gain a pharmaceutical knowledge of even the few remedies he prescribes. It is not "manipulative skill" that he lacks, but actual knowledge, which the pharmacist gains by hard study from his works on pharmacognosy and pharmacy.

Very truly yours,

H. M. WHELPLEY, Ph.G., M.D.

ST. LOUIS, MO.

REVIEWS.

A MANUAL OF CHEMISTRY. FOR THE USE OF STUDENTS OF MEDICINE. By ARTHUR P. LUFF, M.D., B.Sc., Lecturer on Medical Jurisprudence and Toxicological Chemistry, St. Mary's Hospital Medical School, London. With 36 engravings. 12mo, pp. 522. Philadelphia: Lea Brothers & Co., 1892.

THE design of this book is to present to the medical student the fundamental principles of chemistry and such detailed facts as he most needs to know in the study and practice of medicine. Upon the whole, the design is well carried out. The language is terse, the style clear, the statements, as a rule, accurate. In the section on organic chemistry there is too much condensation, and

a few additional pages might advantageously be devoted to a preliminary and detailed explication of the theories of structure. Compounds of physiologic or pathologic occurrence in the human organism should not only be mentioned in chemical sequence, but a separate chapter should be devoted to further comment upon them in medical sequence. A few slips are to be noted; for instance, the phrase "trypsin, the ferment contained in the pancreatic juice," might lead the student to infer that the pancreatic juice contained no other ferment. The word gun-cotton, employed in the formula for the manufacture of gun-cotton, is evidently a typographic error. The statement that strontium salts are not of any medical importance is not up to date. The tests for acetone are omitted; and the only sugar-test we found is that with alkaline copper solutions. Fehling's solution is specifically mentioned, but its exact composition is not given. On the other hand, much useful information, not to be found elsewhere without much search amid matter of no value to physicians, is here gathered and set in order. A second edition will doubtless soon be called for, in which minor defects, such as those we have pointed out, may be corrected. We cordially commend the book to medical readers, practitioners as well as students.

The Diseases of the Stomach. By Dr. C. A. Ewald, Extraordinary Professor of Medicine at the University of Berlin; Director of the Augusta Hospital, etc. Authorized translation from the second German edition (with special additions by the author), by Morris Manges, M.D., Attending Physician to Out-patient Department Mt. Sinai Hospital, New York City. With thirty illustrations. 8vo, pp. xii, 497. New York: D. Appleton & Co., 1892.

The author of this book occupies a foremost place among those who have adopted the modern methods of study of disorders of the digestive apparatus, and his lectures may be accepted as an authoritative exposition of the present status of the subject. The translator has done his work well; the smoothness and clearness of the language being in marked contrast with many translations from the German.

Ewald rightly insists that one cannot be a "stomach specialist." The physician who devotes special attention and study to the diagnosis and treatment of disorders of digestion and diseases of the digestive apparatus must have large experience and broad views, or he will fail to appreciate the information gained by his special investigations; while the technique is so simple that anyone should be able to acquire it.

Among the more important practical points is the statement that peptonization is unnecessary in rectal alimentation; that there is no absolute standard for the size of the normal stomach, and hence functional signs must be largely depended upon in the diagnosis of dilatation, *megagastria* being thus discriminated from *gastrectasia;* that chronic gastric ulceration must be recognized as among the conditions favoring the development of carcinoma, especially in young persons, and that the presence of carcinoma cannot be held to be demonstrated by the absence of free hydrochloric acid from the gastric secretions, unless careful observations, extending over a prolonged period, during which a suitable therapy has been employed, are of uniform result. Equally erroneous is it to exclude carcinoma because free hydrochloric acid is found, as, with localized neoplasm and intact mucous membrane, the secretion of this acid may continue until shortly before death. Ewald believes it to be impossible to diagnosticate carcinoma from isolated epithelial cells found in the vomit. He states that even cancer-nests may be closely simulated by detached fragments of the mucosa. The volume is rich in such facts as these, and will repay careful study.

Transactions of the Association of American Physicians for the Year 1892. Vol. VIII. 8vo, pp. xix, 355. Philadelphia: Wm. J. Dornan.

The *Transactions* of this society are necessarily of an interesting and instructive nature—composed as they are of papers read by representative men of the profession in America.

Owing to the limited space at our command, we must be content with a cursory mention of a few facts gleaned from some of the papers that deal with vital questions of the day.

Dr. George Wilkins, of Montreal, Canada, expresses a strong advocacy of the treatment of typhoid fever by cold baths. His favorable views of the Brand method of treating typhoid fever were concurred in by Drs. William Osler, William Pepper, and Charles G. Stockton, in the discussion that followed the reading of the paper. Dr. James Tyson, in the same discussion, referred to two fatal cases treated by this method. In one case death resulted from embolic pneumonia, and in the other from peritonitis succeeding perforation.

Mere mention can only be made of the interesting and instructive paper of Dr. Geo. M. Sternberg, U. S. A., entitled "Practical Results of Bacteriological Researches." It must be read to be appreciated.

In a paper on "The Treatment of Acute Dysentery by Antiseptic Rectal and Colon Irrigation," Dr. W. W. Johnston, of Washington, D. C., concludes that boric acid and carbolic acid are the best antiseptics to use, preference being given to the drug first named.

One of the most instructive papers presented in this volume is that by Dr. Charles G. Stockton, of Buffalo, N. Y., entitled "Misconceptions and Misnomers Revealed by Modern Gastric Research." It is rendered especially so from the fact that four-fifths of Americans suffer from gastric derangement of one sort or another, and any article tending to correct errors in the diagnosis of affections of the stomach or to systematize the nomenclature of its diseases is more than welcome.

"Tube-Casts and Their Diagnostic Value," by Dr. I. N. Danforth, of Chicago, Ill., is a paper that will more than repay the reader for time spent in its perusal.

Finger-prints. By Francis Galton. 8vo, pp. 216. London and New York: Macmillan & Co., 1892.

Although investigated as far back as 1823 by Purkinje, the lines of the palmar surfaces have never before been systematically analyzed. Galton finds that the ridges of the balls of the digits may be reduced to three typical arrangements: "Arches, loops, whorls." These patterns are subject to wide variation as regards

their cores and the individual ridges to infinite minute differences. Throughout life these lines remain unaltered to the smallest detail, and the imprints of the ten fingers thus furnish a distinctive combination for purposes of identification, compared with which the French system of measuring criminals, called *Bertillonage*, falls far short. The "A. L. W." system of classification admits of a simple system of indexing, by means of which any recorded print may be found among thousands, with the same ease as a book in the card catalogue of a library. The inheritance of peculiar patterns is demonstrated and a preponderance of maternal influence is shown in the hereditary transmission of finger-patterns. From the data thus far obtained, the races of mankind do not appear to be characterized by peculiar patterns, although the percentage of arches in the English and the Hebrews differs in the ratio of 13.6 to 7.9, or nearly 5 to 3. While the author does not consider the relative infrequency of arches among the Hebrews to be of fundamental importance, he offers no explanation for it. No indications of temperament, character, or ability are to be found in finger-marks.

Memoranda on Poisons. By Thomas Hawkes Tanner, M.D., F.L.S. Seventh American, from the last London edition. Revised by John J. Reese, M.D. Small 8vo, p. 177. Philadelphia: P. Blakiston, Son & Co., 1892.

The well-deserved popularity of this little book is indicated by the fact that this is the seventh American edition. Some new facts are introduced that have been brought out since the publication of the previous edition, and the nomenclature has been changed to conform with modern terminology, while matters that had become obsolete have been judiciously eliminated. The subject is of the greatest importance to the practitioner, and the student cannot too early in his career make himself thoroughly familiar with it. The knowledge is of a kind that is useless if not ready. This little book will be found to be accurate and sufficiently complete to meet all ordinary emergencies. Its size makes it convenient for constant carrying in the pocket. It should prove indispensable to all that require a concise, systematic and accurate grouping of the symptomatology, diagnosis, and treatment of cases of poisoning.

First Aid to the Injured and Transportation of the Wounded. By Henry G. Beyer, M.D., Ph.D., M.R.C.S., Passed Assistant Surgeon, U. S. N. (Proceedings of the United States Naval Institute. Vol. XVIII, No. 3.)

In recent years quite a number of books on emergencies have been written, and doubtless have been the means of directing general attention to the importance of giving intelligent instruction on the subject to those whose life-work renders them liable to be called upon at any moment to minister, as best they can, to some comrade stricken down beside them. The naval cadets at Annapolis, to whom the lectures before us were delivered, were fortunate in having the subject presented to them in an exceptionally clear, practical, and interesting manner.

Dr. Beyer wisely begins his course by explaining the nature, causation, and prevention of infectious diseases; then speaks of bacteria in their relation to wounds; and completes his foundation by dwelling upon antisepsis. After imparting some necessary information on anatomy and physiology, and giving instructions on the art of bandaging, descriptions are given of the various injuries —wounds, sprains, hemorrhage, shock, fractures, etc., etc.—with very clear directions as to the recognition and temporary management of each. The effects of heat and cold, drowning, sunstroke, and kindred casualties then receive their just share of attention, and the lecturer concludes his course by devoting the last lecture to the methods of transportation of the sick and wounded.

We take pleasure in saying of these lectures that they constitute one of the best books on "First Aid to the Injured" that can be found. They are written in a lucid and pleasing style, and all of the important points dealt with are illustrated by excellent cuts.

NEWS ITEM.

The Prize Essay on Homeopathy, by Dr. Browning, is now ready for distribution. It forms a neat pamphlet of thirty-three pages, and will be mailed, postage paid, at the rate of seventy-five cents a dozen copies—the cost of printing and postage. Orders may be addressed to Dr. George M. Gould, 119 South Seventeenth Street Phila., Pa.

Books and Pamphlets Received.

Phthisis in Relation to Life Assurance. By Thomas Glover Lyon, M.D. Pamphlet. London: Chas. & Edwin Layton, 1892.

ORIGINAL ARTICLES.

PERSISTENT STIGMATA RESULTING FROM CUTANEOUS DISEASE.[1]

BY JAMES NEVINS HYDE, A.M., M.D.,
PROFESSOR OF SKIN DISEASES IN RUSH MEDICAL COLLEGE, OF CHICAGO.

IN the pages that follow it is designed to call attention to those morbid appearances of the surface of the body which are the persistent relics of cutaneous disease. The word *stigma* is employed in this connection in the broad sense defined by the lexicographers, as the equivalent of a mark or sign. The stigmata that bleed, and to which this name has been restricted by certain writers in medicine, are not here included.

The special field, therefore, to which the attention is asked, is that of the persistent surface-markings of the hairy, and so-called non-hairy, portions of the body, which are the evidences, not so often of a disease that exists as of a disease that has existed, and, having undergone involution, has vanished, leaving, so to speak, its footprints behind it.

Surely there is here no need to urge strenuously the serious importance of the theme. It has a practical value for every physician and for every surgeon. There is no diagnostician, no oculist, no obstetrician, no examiner for the military service, for pensions, or for life insurance, who, for a moment, can afford to be ignorant of the object-lessons furnished by a dead disease. The knowledge to be gained by a study of these details has, at times, solved the problem of life or death; at times it has lifted one physician, struggling in a slough of doubt, to the solid ground of certainty; and it has furnished the clue by following which another has trod the pathway to his most brilliant and triumphant successes. He who is ignorant in these matters is indeed handicapped as against competitors.

In the brief time at my disposal I cannot venture upon an exhaustive discussion of this subject. I shall attempt to touch merely a few of the salient and interesting questions that it suggests. You are, indeed, all familiar with the ground, otherwise you would not be physicians and members of this honored association. All I can hope to do here is to awaken your interest by glancing at some of the facts which our common experience has collected.

[1] An address delivered, by invitation, before the Wisconsin State Medical Society, 1892.

The persistent stigmata of the skin are symmetrical or asymmetrical, generalized or circumscribed changes in the pigment or texture of the derma; a superfluity or absence of the pilary growth on the hairy parts; and scars, scar-like, keloidal, or atrophic patches following inflammation, perverted innervation, new growths, invasion of microörganisms (chiefly the obligate parasites), ulceration, gangrene, atrophy, and the growth of vegetable fungi upon the bodily surface.

The stigmata thus produced differ both as to frequency of occurrence and importance. Some are scarcely more than morbid curiosities—such are the milky skin and snowy hairs of the albino; some are pure disfigurements—such are the oddly notched patches of baldness seen very rarely over the occiput, temples, or vertex of the subject of an ancient and obstinate but departed favus; others again are almost of a physiologic type, and among these may be enumerated the symmetrical baldness of the scalp of the old man, and the atrophic striæ in the abdominal integument of a woman, visible during life after a first pregnancy.

All these tell their own story, and tell it very plainly. We read it daily with scarcely an effort. Some are even recognized at a glance by the profane, and are interpreted with greater or less accuracy, according to the education of the observer. Others are of greater significance for the practitioner. They are persistent stigmata of diseases that have been, it is true, but are also traces of a disease that, though vanished for the time, may have its reawakenings. They may furnish the tokens of a disease that, having done its worst in one region of the body, may yet attack another. It may be the last that attracts our attention—for the relief of which, indeed, we are summoned. It may, however, be the former that will indicate to us the nature of the process.

Without question, the stigmata of first importance in this view are scars. They have been well defined as new-formed substitutes for lost connective-tissue. A disease that leaves a scar is a malady whose lesions have invaded and destroyed a few, at least, of those connective-tissue cells that are ingeniously woven into the basket-like structure we call the true skin. We cannot tell how many must be destroyed, or how deeply the destructive process must advance, before indelible scarring results. We only believe that some scars are transitory and some persistent.

But we may be pretty confident that the eye of the microscope, if properly directed, would recognize a persistent scar in any skin where a needle has once been thrust down completely to the panniculus adiposus. It is true that we say, metaphorically, that Nature delights, as the years slip by, to smooth out the deformities and obliterate the signs of damage done in the past. But, for all this, the fact remains that a pin or a needle thrust into the skin of a child may leave a mark which can be recognized in the dead body half a century or more after the infliction of the traumatism.

It has been said that if one could be suddenly transported to the city of London in the beginning of the present century, and be enabled when walking its streets to observe the pedestrians on its sidewalks, he would be first surprised, not so much by the strangeness of their dress, of their speech, or of their manners, as by the fact that such an enormous proportion of them bore upon their faces the disfiguring scars of smallpox. It is probably within bounds to say of the closing years of the century that, if we were enabled to scan the naked bodies of all the pedestrians on our streets, it would be seen that the scars produced by syphilis far outnumber those produced by smallpox. In the last-named disease the scars are more conspicuous because thickly set over the face; in the other, the scars are more often formed on the lower extremities, and are therefore not exposed to the eye of the casual observer.

Every physician should be so thoroughly familiar with the scars left by syphilis that, if need be, he could swear in court to their character. When perfectly typical they resemble nothing else in the entire scope of pathology, except a relic of the syphilitic process. Let us look at them carefully for a moment, and then at their value in a diagnostic view.

First, then, they are often elegantly rather than clumsily wrought. The ulcers of late syphilis are often so formidable and threatening that one who is not expert will not foresee how delicately and beautifully repair will be accomplished and the evidences of mischief smoothed away after the lapse of five, eight, or ten years. Even the rift in a mountain or rock is partly filled by its own detritus after the storms of a few seasons have swept over it.

Second. As syphilitic ulcers are commonly rounded in outline, so these peculiar scars are in circles, or parts of circles, giving us the semilunar, quarter-moon, and gibbous outlines, with combinations representing the figure 3 or 8, the letter S, the form of the kidney, of the horseshoe, and of the dumb-bell.

Third. The pigmentation they exhibit is peculiar. It is best studied naturally in the lower extremities, where, as in the cicatrices following traumatism and healed varicose ulcers, the staining from coloring matters brought thither by the blood effused in excess in and about the part is most conspicuous and persistent.

I think there is no question but that both individual and race peculiarities influence the degree of this staining. It is marked in many deep brunettes; it is rarely as disfiguring in very light blondes. In the scars of syphilis, which we are now studying, the color in the cicatrices following freshly-healed ulcers is at first that simply of hyperemia, dull-reddish, purplish-red, occasionally even pinkish-red. As the infiltration subsides the color becomes more apparent, till we have every variation, from the deepest chocolate to the lighter brown, evenly tinting the scar-tissue, and in some cases more than others staining the integument beyond the outer wall of the cicatrix, forming with a species of pigmented halo, half or a full finger-nail in width, and corresponding in shape to that of the ulcer which preceded, semilunar, kidney-shaped, etc.

After a period lasting from a few months to as many years, the process of discoloration begins in these singular-looking stigmata, the difference of time depending largely upon the general vigor of the patient, and upon the occupation—a prolonged observance of the erect posture, as in wheelsmen of vessels and train-drivers, being unfavorable to rapid removal of these coloring matters.

The entire process of decolorization may be concluded in three or four months, but may require a much longer period. It has occurred to me that it is more rapid in women than in men, but of this I am not positive. A completely decolorized scar of the leg, wholly destitute of undue pigmentation, in a male patient of average weight and vigor, commonly points to a syphilitic infection from six to twelve years previously, unless the decolorization has been completed and the scar has remained practically unchanged for some time. Then, of course, one can often verify the fact that fifteen, twenty, or twenty-five years have elapsed since the date of infection.

Let us look for a moment at this wholly decolorized scar. It is perfectly distinct texturally, though suggesting to the scientific eye that can read its past history, that it is faded. It is smooth, unattached, occasionally picked out in points, as though one had treated it with the tool of the engraver or the burin of the etcher. Its color is that of the familiar dead-white of an old scar; but very rarely indeed is it rigid, puckered, or elevated as in spurious or true keloid. Occasionally, even when ancient, there is an appearance at one or more points of a thin scale, which may be detached from its surface. Its conspicuous features are its delicacy and its thinness. It may, with great readiness, be plucked up from the

tissue beneath, between the thumb and finger. It is best compared with a thin sheet of mica lightly let into the skin. It is very slightly depressed beneath the general level of the integument.

Repair has been so finely wrought in such a case that as one sweeps the fingers over the surface it can scarcely be recognized by the touch where the new-formed tissue exists; and the movements of the limb may not cause the slightest puckering of the skin where the scar is formed. It answers admirably all the needs of the part, save that it does not furnish sweat or other secretion in normal measure, and but few if any hairs appear upon its surface. Who would suspect, upon examination of this superficial and at first sight insignificant patch, that it had been once the seat of a deep, exquisitely painful and even formidable ulcer, boring within to the very lowest stratum of the panniculus adiposus, and causing in some patients more apprehension than a fractured leg or an apical pneumonia?

There are some variations of this typical portrait that must be studied in order to compass our end. Almost every syphilitic cicatrix of the size of the section of an egg or larger, if examined with care, will be found to be made up of a congeries of smaller lesions, each of which is possessed of the characteristics of the larger. The mode of grouping of these smaller scars, each, perhaps, as large as a thumb-nail, is quite in accordance with the law of the circle we have been studying. Sometimes, rather more rarely than in the other forms that we have to notice, a large central lesion is surrounded by a circlet of the smaller, suggesting the familiar arrangement seen in a brooch set with pearls. Again, we have the so-called "satellite" figures, a larger patch, with one or two of the smaller set on at the edge; or the figure is strikingly like that of a trefoil or quatrefoil slightly distorted from the strict architectural pattern. At times the patch is made up wholly of these small circlets, compactly gathered within an oval, roundish, or circinate outline, the compound lesions conforming in every detail to the description given.

Studying these combinations, whether in the figures selected for illustration or in the S-shaped, kidney-shaped, or often variously shaped figures, we find that each component element of the group may be recognized as to age by its separate decolorization-process. In a patch of this kind one may at times see that the process of whitening is going on at nearly the same rate in each scar, all for example at the moment of observation being provided with a tolerably clear or clearing center, and a reddish or purplish rim outside the latter.

It goes without saying that the still highly tinted and not wholly decolorized cicatrices of syphilis are often seen in combination with, or in close juxtaposition to, the ulcerative or resolutive lesions that originally produced them all. Thus in a circinate group a cluster of finger-nail-sized scars may form the crescentic border of a patch the corresponding incurved border of which is made up of healing ulcers where gummata have softened, each a miniature as to outline of the scar that will succeed. A consideration, however, of these unhealed lesions would lead us too far from our present purpose, that, namely, of viewing only the stigmata that persist.

Studying these interesting relics of disease in other regions than the lower extremities, we discover always the same general characteristics, with differences due largely to peculiarities of situation. On the other extremities, for example, we find scars of the same type, but with very much less pigmentation, and this latter, when at all conspicuous, is removed in a far shorter time than elsewhere. Thus a group of shallow and depressed, circular bean-sized scars, a dozen or more in number, may be seen over one or both of the olecranon processes (a common site) quite destitute of color in six months after their first development; and the same may be said of a large saucer-sized and saucer-shaped patch that may be seen over the point of a shoulder, near the clavicle, in front of the upper chest, or, not rarely also, over one hip—all favorite sites of this peculiar disfigurement.

It is on the face that the characteristics we have been studying are first lost, and where confusion is most likely to arise. The causes are, *first*, the frequent absence, for more than a few months at the most, of the pigmentation; *second*, the configuration of the folds of the skin of the face, making irregularities in the surface; and, *third*, the interference with the natural progress of repair, often mischievously directed, in order to overcome at an early hour the too evident impairment of personal comeliness. The chief variations from type are as follows:

1. The multiple and almost symmetrical small (pea-sized and larger) scars left by resolving or ulcerating tubercles. These are likely to be confounded with the scars of variola, on account of their great number and the absence of the typical features of the scars we have been studying on the lower limbs. They are often no larger than peas or beans, are somewhat symmetrically, at times very irregularly, strewn over the face, and are set into the skin about as deeply as the cicatrices of the same region left by smallpox. But the differences between the two, however close may seem the resemblance, are on careful observance apparent.

The syphilitic scars of this order are seen more often and more abundantly upon the upper half of the face, while the variolous relics are more generally and impartially diffused. In syphilis the

scars affect the brow preëminently; and after this the temples, the outer nares and the outer angles of the lips; often the tip of the nose, the center of the upper lip, and the entire chin are spared. The marks of smallpox are often conspicuous in these last-named regions, and in well-marked cases are thickly and uniformly spread over the whole countenance—an exceedingly rare occurrence in syphilis.

2. The single, small, or relatively few larger deforming scars of the face more nearly approach those of the type studied on the lower extremities. These are illustrated by the crescentic cicatrices visible a short distance from the angles of the mouth, set into the skin of the cheek, the convexity turned toward the angle of the jaw, the concavity or plane outline next the mouth. These may be an inch or more in diameter, and when closely studied exhibit the traces of the gummatous ulcer in outline and superficial erosive action. Such scars, too, are not very rarely displayed upon the lower brow, as if one had taken for a center the point of exit of the supra-orbital nerve from its foramen on one side, and swept over the brow a semicircle with a radius of half an inch or more. A smaller scar of this type is formed in some patients in front of the ear, looking something like the outline of a seashell, semi-crescentic in contour and not larger than a thumb-nail.

3. Lastly, the wholly irregular scars of the face, the difference of which in type from all those previously described, is due either to traumatism or to the influences of special traction in the performance of the functions of the facial organs. Here may be named the strictly linear scars, vertically directed along the brow where scratching has occurred, or when the finger-nail has torn off a crust and with it a portion of the integument, directing the ulceration in a peculiar line. This is of the rarer type. Much more common, and, for the purposes of diagnosis, much more important, are the so-called lines of puckering at the outer angles of the lips. These, when typical in the adult, are not one whit less significant than when seen in the infant affected with inherited disease; and are usually due to the same cause, viz., the occurrence of ulceration as a complication of mucous patches in the muco-cutaneous folds about the angles of the lips. They are always radii from the long axis of the oral cavity, rarely proceed to any distance from the verge of the mouth, and present an odd-looking, puckered appearance that persists through life. So far as is known to me they are absolutely diagnostic of syphilis; I have never seen them, with characteristic features and when affecting both angles of the mouth, in any other disease.

In this same group may be named the exceedingly irregular, small-sized, isolated scars of syphilis found upon the face. These are jagged, single depressions, one or two of which exist in some patients on the sides of the root of the nose, on one cheek or both, or in the region of the beard in the male subject.

It was once held by some excellent diagnosticians that the *alopecia prematura* of the scalp in the third decade of life was suggestive of syphilis. We now know that this was a palpable error. It is a demonstrable fact that there are no forms of baldness of the hairy scalp so amenable to a proper treatment, so often, indeed, remedied without any treatment, as the early symmetrical alopecia of recent syphilis. It is, however, far different with alopecias of late syphilis. These are all due to cicatricial lesions, or those going on to the production of cicatrices. Here we have a distinct recurrence of our type studied in the leg. On examination the scar does not, at first sight, stand out so conspicuously as upon a non-hairy surface. We have to separate the adjacent hairs in order to gain a view of it. When fully disclosed it is seen to be our old friend, and with scarcely an attempt at disguise. There is the crescentic border, the reddish or purplish hue of the surface not long healed; the deeper purple for a brief time after the healing; then the relatively rapid decolorization; lastly, the dead-white or dull-white scar, with, perhaps, one or two hairs only growing in the center of the bald patches, which are as large as a silver dollar, or the section of a hen's egg. This is the seat and explanation of the irremediable alopecia of authors, due to late gummatous involvement of the scalp.

Lastly, in this hastily-enumerated list, must be named a scar of interesting features, belonging, however, to quite a different period of syphilis, and due also to causes different from those heretofore considered. At no very remote date examiners for the military service of the United States Government were cautioned to search for scars upon the penis as signs of chancres. Let us hope that in this late day they are wiser in these matters. It is well known that the immense majority of chancres on the progenital region of the male leave no scars. The initial sclerosis is usually resolved, leaving no trace behind it of the primitive accident. The majority of cicatrices left in this region as sequels of venereal accidents are those of chancroids, the so-called "soft" or contagious, auto-infective pustular and ulcerative lesion of this region.

It is well known, however, that continued irritation of the initial sclerosis of syphilis may cause it to ulcerate so deeply that it will erode the connective tissue of the derma to an extent sufficient to leave a scar. Savin cerate, caustics frequently applied, and spontaneous gangrene (rare of occurrence, indeed) may induce this erosion. There is,

however, one initial sclerosis that is the seat of well-nigh constant irritation till its usually long-deferred healing is completed, and that is the infecting chancre seated immediately within the meatus urinarius. One very emission of the urine its surface is covered by a fluid highly charged with urinary salts, and the pain of micturition is correspondingly great. The diagnosis of this lesion, when in activity, is made with the greatest ease, without the aid of the endoscope. When the tip of the glans is manipulated by the finger and thumb of the surgeon, the sclerosed mass of the chancre is distinctly felt as though it were a cylindriform mass, no larger than the stem of a common clay pipe, and scarcely as long as a digital phalanx and substituted for the normal urethral channel. The incessant irritation at last produces scarcely so much ulceration as it does a deeply-seated erosive action, which results in reaming out the meatus urinarius. When all is healed the apex of the truncated cone, represented by the tip of the glans, is seen to be lost. The acorn-shaped body is destitute of its delicately-finished tip. It has an obtuse or blunt apex; and the perfect accuracy of adaptation of the lips of the meatus is forever lost. Instead, there is an odd-looking funnel-shaped gap of the mouth of the conduit, with the flaring end of the funnel directed toward the eye of the observer. This, too, in my experience is produced only by the syphilitic chancre. The gangrenous or deeply ulcerating chancroid will mutilate the glans in the most lawless manner, remove one-half or more, or even the whole of the organ, in the most irregular way, will gouge out one side or the other, and leave the urethral orifice as a chasm where once the frenum stretched its slender arm for the suspension of the scrotum. But almost never will the process cease with the delicate reaming described. Cicatrices in the groin of one or both sides have no significance for most cases, as regards the diagnosis of syphilis.

It is the diagnostic importance of stigmata like these that makes them especially interesting. Let us glance for a moment at a few pictures drawn, like the silhouettes of the artist rather than in the serious style of the time-honored "reports of cases," each of which without much detail may illustrate to a degree some point to which our attention has been already attracted. Each has this merit at least, that it is drawn directly from practical experience, and represents a serious fact in pathology.

1. A healthy-looking young widow, with a history of eczema of the left elbow one year before, has an infiltrated patch upon one naris threatening the integrity of the whole organ, from which she has suffered for months, and which has been pronounced lupus by four physicians of acknowledged repute. One of them has administered an anesthetic and thoroughly scraped the lesion, without benefit. The physician last consulted insists on a careful examination of the elbow where the so-called eczema was located the year before, and he recognized at a glance typical multiple and bean sized cicatrices grouped in a circle, with two outlying "satellites." He thus fortifies the correct diagnosis of the nose-lesion, and, after administration of appropriate remedies, the nose is healed in a month, the sole deformity resulting from the abortive scraping.

2. A ruddy-faced merchant in middle life, the father of healthy-looking and wholesome children, lies in bed suffering from atrocious retro-sternal pains that have lasted for a week, and for which he is vainly treated by two physicians, both believing that the pleura is seriously involved. The patient becomes hourly worse, and describes his pains with an eloquence that in itself is suggestive. A consultant, being summoned, makes a more careful examination of the person and recognizes a decolorized, circular, and typical cicatrix, reported to be twelve years old, over the left thigh. It is of the large single pattern, unattached, smooth, and free from ribs and puckerings. Diagnosis is made of a retro-sternal gumma, which is properly resolved, the pain subsiding in three days under efficient doses of the salts of iodine.

3. A gray-haired lady of social position, sixty-five years of age, widowed for fifteen years, is a helpless wreck, unable to use hands or feet, wheeled about in a chair by her maid; she has had an elevator built in her home to enable her to visit her dining-room with her children. She had been treated without avail by many physicians for ten years, and then, growing steadily worse, she abandoned hope and settled herself in her chair, anxious, during her remaining years to brighten with her mental qualities the domestic atmosphere in which she lives with her two sons. The morbid condition of the nervous centers has resulted in distorting the fingers so that they are curiously twisted into the palms, and the toes are similarly affected. Spurious ankylosis has rendered the larger joints useless. At the last a physician is summoned for relief of the annoyance caused by a successive shedding of one or two of the finger-nails, and he is sufficiently interested to explore the case thoroughly and in all its details from the beginning. He discovers two typical cicatrices on the inner faces of the tibia, wholly decolorized, which plainly declare that the entire train of symptoms began with luetic infection by the husband twenty years previously, with serious results, as respects the nervous centers, all of which might have been averted by an appropriate therapy at an earlier date. Under the treatment now pursued the nails are no longer shed, and some use of the fingers is regained.

4. A California superintendent of mines, vigorous of constitution and brawny of limb, comes to the city for the purpose of having an epithelioma removed from his upper lip. The date is fixed for the operation, but the day before that date he chances to consult another physician than the one selected for the operation, in order to verify the diagnosis. The patient is now stripped, and after examining the

whole body, as well as the lip, with care, there is discovered a scar over the elbow, in consequence of which the operation is deferred a fortnight. The result is that the lip is healed without resorting to the knife.

5. A young and childless wife, of fair nutrition and good general health, consults her physician for an egg-sized tumor which has slowly formed in the mass of the right breast during the preceding six months. She is naturally greatly alarmed lest she be the victim of carcinoma. An examination is made with care, the result being that two or three firm subcutaneous marble-sized nodules are recognized near the left elbow, where there is also a group of pea-shaped cicatrices that indicate an infectious disorder. The gumma of the breast is made to disappear after appropriate internal and external treatment.

6. A middle-aged dentist is in his bed and supposed to be dying, his wife, mother-in-law, and other relations weeping over him. His physician has been faithful in attendance for three weeks, but the patient, in spite of all treatment, has grown steadily worse. He lies supinely, breathing slowly, and is insensible, and incapable of performing the acts of deglutition; the pupils are dilated. By tickling the soles of the feet certain reflex movements can be excited. The temperature is not abnormal. The pulse is somewhat accelerated. A consultant, after securing details of the history of the case, strips and examines the body with special care. A reamed-out, funnel shaped meatus urinarius is discovered, with the result that a tenth of a grain of calomel is placed every hour on the tongue of the man supposed to be dying, and in three months he goes to Europe for the restoration of his health, and in two years is the father of a handsome baby.

7. A well-developed young Englishman, twenty-five years old, whose case has been pronounced lupus by half a dozen of the most eminent physicians of Great Britain, including the consultants of some of the largest London hospitals, applies to a competent surgeon for the amputation of his right arm. The limb is so tumid, distorted, and clumsy, and its fingers are so twisted and misshapen as to render the member worse than useless. It is actually so much in the way as to encumber him in the work he is yet capable of doing with the sound arm of the other side.

The surgeon, before deciding upon the proper course, consults with a diagnostician. The latter strips his patient and examines him from head to foot with scrupulous care. He discovers upon the posterior surface of the left thigh a dinner-plate-sized circular scar, with pigment not yet wholly removed from the center, and some odd-looking crusted lesions at the periphery of the circle. The man is vigorously treated for gummatous infiltration of the offending limb, with the result of rapidly reducing it in size to a point where amputation is not even considered.

Illustrations of this sort might be multiplied almost indefinitely. They indicate with clearness that there is scarcely any problem presented in any department of medicine or surgery which may not be solved by a discovery of one or more of the stigmata to which we are now directing attention.

Perhaps it will be more useful, in the time that remains, instead of noting the points of differential diagnosis between the scars of syphilis and those of other diseases, to glance briefly at some of the characteristics of the persistent stigmata likely to be confounded with those we have been studying.

The scars of herpes zoster (shingles), whether on the face or body, proclaim themselves to be such, almost at the first glance, by the rule of their symmetry. This rule is almost never violated save when we have zoster of the region supplied by the fifth nerve, and this is such a curiosity that very few even of experts have seen it. The cicatrices (which do not result in all cases) are so distinctly arranged along the lines of distribution of the nerves of one side of the body that one can scarcely confuse the groups of indented scars, each suggesting that it had been made by some such instrument as a carpenter's nail-set, with the irregularly packed and less defined, as also less deeply depressed and symmetrical scars of smallpox. In shingles of the region supplied by the supra-orbital nerve there are in some cases not merely persistent relics of the disease in the skin, but traces of damage inflicted upon the eye in the form of corneal opacities, and even destructive changes in the deeper structures of the globe.

Looking, then, at the three prominent disorders producing cicatrization of the skin of the face, we have: Smallpox—its scars almost invariably symmetrical and general; those of zoster, almost without exception symmetrical and never general, but always in the areas of distribution of the facial nerves; and those of syphilis, sometimes symmetrical and sometimes not, but never distinctly limited to areas of nerve-distribution, and, whether occurring on one or both sides of the face, selecting (as the other diseases named never do) the regions near the corners of the lips and lids, and the upper in preference to the lower portions of the face. In any event, if few or single, and in one region only, they represent a diversion from type rarely encountered in the other diseases here named for the sake of contrast.

The scars of obstinate, persistent, and vanished facial acne are often general and symmetrical, but never of the defined and deeply-set character of those of variola, syphilis, or zoster. They are, moreover, distinguished in all severe forms by the peculiar keloid-like ridges into which several of them are converted. The puckered, elevated, corded, and ribbed irregularities of either cicatrices or the tissues between the latter, are well-nigh pathognomonic. In case of doubt it may be well to remember as to these pictures of an ancient, rebellious, and ill-

treated acne, that when the inflammatory processes have all ceased and there are left only stigmata upon the field where the battle was once fought, there is almost, without fail, a similar picture presented upon one portion or another of the dorsum of the chest, where also, usually, the keloidal complication is seen to best advantage in exaggerated forms.

The scars of lupus need never be confused with any of those thus far considered. In lupus vulgaris the cicatrix always possesses a distinguishing absence of special peculiarities. It is by this that it is best known. Mr. Jonathan Hutchinson was once pleased to describe syphilis as an "imitator" of other diseases. Lupus vulgaris may be said to imitate nothing, not even itself! The scars left in this day, when lupus is in so many cases satisfactorily managed by modern methods, is really the scar produced by the treatment of the malady. The processes of erasion by the sharp spoon, of destruction by the Paquelin knife, by caustics, by scarification, or by the later chemical combination of salicylic acid and creasote, leave cicatrices of all sorts, marked by their exceeding irregularity. In almost all cases these are wonderfully smoothed away in the course of time as the young girls, who constitute the majority of patients thus afflicted, advance to the maturer life of womanhood. It is, indeed, remarkable that, in a decade after a nose has been half eraded or wasted, if there be actual arrest of the disease the deformity is to such a degree hidden by well-rounded, even well-tinted cheeks, and the comeliness of the unaffected portions of the face. For other cases there are only the most irregular and deforming stigmata, scars more disfiguring than those of severe burns, everted or contracted lids, noses reduced to absurd miniatures of their former selves, or moulded into the familiar pattern of the parrot's beak, with the tip carried down toward the upper lip, and the nares on either side wasted as if carved into the lateral cavities by the chisel of a caricaturist! The same may be said of the ear, which has been fastened to the cheek or reduced to a mimic and mutilated image of the organ in health. Fingers, toes, and hands undergo similar changes, with deformities defying description, comparable only to the frightful ravages of lepra. In all this we find no law; only a lawlessness that attracts our attention to the very fact of its defiance of restriction.

In lupus erythematosus, more particularly of the face, in which cicatrices are most often observed, the result is far different. Here we have an aid to diagnosis, the special configuration of the patches of the disease producing the characteristic "butterfly's wing" appearance, the scar representing the body of the insect stretching along the bridge of the nose, while the scars corresponding to the wings are spread over the cheeks, one on either side. Here the scar is superficial, well defined, at times symmetrical, decidedly preferring the nose and adjacent parts of the cheeks, but involving also the lids, the lips, the ears, and the scalp. When the disease is at an end the scar is thin, whitish, very slightly depressed, very definitely outlined, and at times looks as if it had been picked out with the engraver's tool—that is, pointed here and there over its surface; each of these points probably representing the orifice of the excretory duct of a sebaceous gland. The scars are often very delicately finished, and especially on the hands and fingers may at times be represented by delicate, whitish cords, linear in shape, and, as to length, relatively short.

Upon the lower extremities the cicatrices representing ulceration due to varicosities of vessels, and often an accompanying eczema, may be as deeply pigmented as any of the relics of syphilis in the same region. Indeed, in well-marked cases the deep chocolate-brown staining is in the former instances more distinct. But, if closely scanned, one can recognize in the non-specific cases an indefiniteness of outline at one point or another, while the typical syphilitic cicatrix already described is wholly absent. In making a differential diagnosis it should always be remembered that with the lapse of time the eczematous and varicose conditions, as a rule, present the portraits of more severe damage than the syphilitic lesions; because, however deep and grave the gummatous ulcer, it is, in the course of time, so exquisitely smoothed away that its traces are superficial, wholly decolorized, and non-attached. On the other hand, the formidable-looking ravages in the lower limbs, marked by extensive and irregular scarring, by much more persistent and deep pigmentation, by attachment of cicatrices to the deeper structures, and, especially, by the varices of vessels in the neighborhood, are generally of non-specific origin.

There are very rarely seen on the lower limbs, or the surface of the thighs more often than of the legs, one or several lesions looking like scars, which are not such, and which are often erroneously interpreted by those who are not expert in the recognition of cutaneous stigmata. These are the odd and interesting discs of morphea, named, according to the teachings of a later pathology, "circumscribed scleroderma." When perfectly typical, these atrophic, scar-like, dead-white, ivory-white discs, rarely larger than the half-section of a hen's egg, have a very distinct contour, bordered with a violet-tinted zone. When examined closely, this belt is seen to be constituted of a delicate plexus of minute vessels. This zone is rarely more than a line or two in width. The surface is either smooth and on the level, or

at times even slightly elevated above the level of the surrounding integument, with occasional punctate marking over the patch. When, as in the case selected for illustration, there are several such patches, they are seen arranged in the line of the long axis of the limb and according to the distribution of the nerves. They are usually unilateral, and may be seen upon the head, the face, and elsewhere, though more rarely even than on the lower limbs. The non-attachment of the diseased patch to the substructure of the integument, the general absence of hairs and of secretion, and the occasional coloration of the patches, which in the end may be markedly depressed below the general level, increase their resemblance to scars. They may not, however, in all cases prove to be persistent stigmata, as they occasionally disappear spontaneously or under treatment. In some cases the attachment to the deeper structures is conspicuous and disfiguring.

Allied to these curious patches are the striæ, and even lesions of circular outline, which are recognized as simply linear and macular atrophies of the skin. The lines observed upon the abdomen of women after pregnancy are of this particular order; and it is interesting to note that in rare cases they may be seen fully as conspicuous on the abdominal surface of the healthy adult male subject who has never suffered abdominal distention from disease.

The white patches of vitiligo, or leukoderma, as the disease is termed by some authors, are so well known that the merest reference to them is here needed. They occur as rounded, oval, or irregularly curved patches, one or many in number, with the pigment wholly removed from the disc, which is left of a dead-white color, as are also the hairs which chance to grow upon the affected part, the pigment being heaped up in excess about the convex circles limiting the edges of each. These may develop upon any part of the body and at all times, and slowly spread by multiplication and coalescence till a large part of the bodily surface is successively whitened, as in the piebald negro, whose skin, in exceptional cases, becomes well-nigh dead-white. The chief reason for naming these lesions in this connection is to call attention to the striking fact that they are actually among the persistent stigmata of the skin. They are usually most conspicuous in summer, it is true, partly on account of the change occurring in the pigment of the border under the influence of heat and sweating. Occasionally the reverse is true, that they are most conspicuous in winter, and least so in the heated term. But, as a matter of fact, the bleached patches never acquire the pigment they have once lost. If there be any method of reawakening the mysterious forces by which pigment is produced in the patches whence it has once been removed, certainly none is known to science in our day. A knowledge of this fact may save much disappointment to those patients who may still be found making local applications to vitiliginous patches in the vain hope of restoring the natural color, or, what may be justly described as worse, who are swallowing drugs in the delusive hope that they may compass the same end.

Gentlemen of the Society, I close with an expression of regret that I have been able to touch at such few points and so imperfectly, the vast, important, and interesting field suggested by my theme. I shall be well content if, by these fragmentary remarks, I have attracted attention to any part of it. If a visitor from another planet than ours, interested in our scientific methods, were to question one of us on the subject of these stigmata, I can imagine him saying: "As the internal organs of the body are all hidden from view within its living envelope, I suppose that most of your physicians are better acquainted with the diseases that are betrayed on the exterior than with those that affect the viscera, such as, for example, the lungs, the liver, the heart, the kidneys, or the bladder." Imagine his surprise on hearing the response: "You are quite in error. The average physician on this planet we call the earth will frankly admit to you that he knows a great deal more of the disorders of internal organs than of those betrayed in the surface-markings of disease that are spread before his eyes."

TRAUMATIC LESIONS OF THE SPINAL CORD.[1]

BY GEORGE J. PRESTON, M.D.,
PROFESSOR OF PHYSIOLOGY AND DISEASES OF THE NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

INJURY to the cord, resulting from external violence, is of rather more frequent occurrence than would be expected if we consider how well protected the cord is. The peculiar construction of the vertebral canal, the strength of the individual vertebræ, the very perfect and extensive articulations with each other, the elastic intervertebral discs separating the segments, and the various ligaments binding the parts together, require a high degree of violence to produce either dislocation or fracture. Added to this the spinal canal is much larger than its contained cord, and the latter is consequently not in direct contact with the bony walls, but is suspended from above, and steadied laterally by ligaments and emerging nerves.

The most common form of injury to the cord is that which results from fracture of the vertebræ. This accident occurs as the result of a general crush, as by a fall of coal in a mine, or of earth or stone in a tunnel or quarry; also by external violence applied at

[1] Read before the Clinical Society of Maryland, December 16, 1892.

one point, as when a man is caught between cars. Not an uncommon cause is a fall, which may cause fracture of the vertebræ either directly, as when an individual falls flat upon the back, or indirectly from striking upon the head or feet, the force of the fall being felt most strongly at certain points along the vertebral column. Extreme flexion of the body, or twists, may produce dislocation or even fracture. Gunshot wounds involving the vertebræ, while not very common in civil, are often met with in military practice.

As a result of these and similar injuries to the bony structures, the cord may be compressed, more or less lacerated, or entirely destroyed. Compression may be occasioned either by the broken bone impinging directly upon the cord in the shape of a fragment or spicule, or by a narrowing of the canal. The points at which fracture is most likely to occur are the cervical and lower dorsal regions, unfortunately the very points where the cord can least afford interference with its function. Compression of the cord may result from hemorrhage within the spinal canal, due to rupture of the spinal veins. Finally, when the cord itself is not injured, the meninges may be torn and the cord suffer secondarily.

In addition to the class of cases already referred to must be added those cases in which, without any fracture or dislocation of the vertebræ, the cord suffers more or less severely. Concussion of the *spine*, or *railway spine*, as this condition is wrongly called, has occasioned a good deal of rather acrimonious debate, largely due to the fact that the subject has been so often in the courts. While concussion of the cord is infinitely less common than concussion of the brain, it undoubtedly does occur, and we may have all grades of injury, from a mere temporary suspension of function up to a considerable degree of laceration, without fracture of the vertebræ.

The symptomatology of injury of the cord is coextensive with the functions of the cord, as any part of the latter may be involved. As far as location goes, we need consider only the cervical enlargement, the mid-dorsal region, and the lumbar enlargement.

In the cervical and lumbar regions are situated the important centers for the muscles of the upper and lower extremities and for the thoracic and abdominal viscera, and entering these portions of the cord are the sensory nerves from the extremities. Injury may therefore involve the nerve-centers or cells, or the white matter alone. In the dorsal region the gray matter sinks into insignificance, and we are concerned mainly with the extent of the involvement of the white matter or fiber-tracts in their passage to and from the brain.

The symptoms of injury to the cord may be divided into primary and secondary. By primary symptoms are meant those that appear suddenly, as the immediate result of the injury—such, for example, as paraplegia. By secondary symptoms are meant those that come on at a later period in the form of degeneration of fiber and cell; this class is illustrated by the various muscular atrophies and trophic lesions generally. In discussing briefly the primary symptoms of injury to the cord, it is necessary first to note those symptoms of a general nature and not dependent upon the location of the injury, and then the special symptoms that depend upon the region involved and the extent of such involvement.

The general symptoms of injury to the cord are few. Shock is present to a greater or less degree, sometimes being marked after slight injuries, and at other times present only to a slight degree, though the injury may have been severe. Consciousness is rarely lost, even in cases proving rapidly fatal. Of particular interest is the rise of temperature, noted especially in injury to the cervical cord, and, in lesser degree, in injuries in the lower dorsal and lumbar regions. No very satisfactory explanation of this phenomenon can be given. If it were met with only after injury to the cervical cord it might be explained on the ground of interference with the heat centers, supposed by some physiologists to be located in that region; but as injury at any level may produce rise of temperature, we must conclude that this is due to interference with the fiber-tracts connected with the heat-regulating centers. Varying degrees of pain may be present, depending upon the location and extent of the injury and the involvement of nerve-roots. Priapism is a common symptom, especially in injuries to the cervical cord. Rosenthal mentions a case of injury to the cervical cord in which the priapism lasted for seven days during life and for thirty-six hours after death.

In discussing the special symptoms, it is important to bear in mind the fact that we may have all grades of injury, and consequently the intensity of the motor and sensory symptoms will vary accordingly. Again, the cord may be involved to a greater degree on one side than on the other, causing a difference in the symptoms of the two sides. When the middle of the cervical enlargement is involved, somewhere about the sixth or seventh cervical vertebra, there is loss of motion in all parts below the level of the lesion, and of sensation over the inner half of the arm and forearm and all below this level. The temperature is always notably raised, the pupils are contracted, and the breathing is diaphragmatic. Lesions high up in the cervical region cause loss of motion and sensation from the neck down, interfere seriously

with respiration, and are usually rapidly fatal. The two following cases illustrate very well the symptoms of injury to the cervical cord: the first case is one of injury to the upper part of the cervical region; the second, of injury about the mid-cervical region.

CASE I.—A male, aged twenty-four, gave a history of having plunged head first into shallow water. When admitted into the hospital, some ten or twelve hours after the accident, examination showed no signs of injury to the head. The head was somewhat retracted and any movement of it caused intense pain. All four extremities were paralyzed, the lower completely, the upper being capable of some slight movement. Sensation was lost from the neck down. Breathing was purely diaphragmatic. The patellar reflex was present, and the pupils were contracted to pin-points. The temperature was 104° F. The mind was perfectly clear. There was priapism and loss of control over the bladder and rectum. Death occurred on the evening of the day he was admitted into the hospital, which was the day following the reception of the injury. The temperature, taken in the rectum four hours after death, was 110° F. The autopsy revealed a fracture of the fifth cervical vertebra. The cord showed laceration at the point of fracture, with extravasation of blood extending about an inch vertically.

CASE II.—A male, aged thirty-seven, fell about forty feet upon a rough, irregular surface. Examination shortly after the accident showed a lacerated wound of the scalp, but no fracture of the skull. He was perfectly conscious. There was complete paralysis of the lower extremities and partial paralysis of the upper. Sensation was entirely lost from the level of the third rib down, and impaired over the chest and arms. Respiration was diaphragmatic. Priapism was marked. There was paralysis of the bladder and rectum. The pupils were finely contracted. The temperature, 103° F. an hour after admission, reached 109° F. just before death, which took place the day following the reception of the injury.

At the autopsy it was seen that the laminæ of the fourth and fifth cervical vertebræ were fractured on both sides; the dura was slit longitudinally and there was an extra-dural hemorrhage posteriorly. The cord opposite the fracture showed hemorrhage and disintegration of its substance.

Lesions in the mid-dorsal region, if complete, cause loss of motion and sensation below the seat of injury. If the lesion be high enough, the arms may be slightly affected both as to motion and sensation, thus approximating the symptoms detailed. When the lesion is only partial, the differences between dorsal lesions on the one hand and cervical or lumbar on the other, become much more apparent. This is very obvious if we consider that in the dorsal cord the gray matter and consequently the centers are very insignificant, the white matter or fibers composing almost the entire cord between the cervical and lumbar enlargements.

A lesion in the lumbar region, involving the lumbar enlargement, causes loss of motion and sensation in all parts below, loss of control over the bladder and rectum, and loss of the superficial and deep reflexes. It must be understood, of course, that the symptoms here detailed are only the immediate ones; the secondary symptoms, such as atrophy and the like, will be mentioned under the head of secondary symptoms. The following cases may be mentioned as illustrative:

CASE III.—A male, aged twenty-three, was crushed by a bank of earth falling upon him. There was no external injury of note. There was entire loss of motion and sensation below the level of the first lumbar vertebra, and loss of control over the bladder and rectum. There was no loss of consciousness at any time. The superficial and deep reflexes were abolished. The temperature on the day of admission to hospital, which was the day of the injury, was 102° F.; it remained at this point for five days, then sank to normal and did not rise again until just prior to death. Bedsores of a trophic nature developed in the gluteal region, and cystitis was also a later complication. The patient was admitted March 26th, and died rather unexpectedly May 15th. The autopsy showed that the last dorsal and first lumbar vertebræ were crushed and dislocated forward, compressing the cord and reducing it to an almost empty sheath.

CASE IV.—A male, aged fifty-two, fell nine or ten feet into the hold of a vessel, striking upon his back and side. There was no loss of consciousness and very little pain, but there was instant paralysis of the lower extremities. Examination showed a scalp-wound, but no fracture of the skull. There was a marked projection of the tenth dorsal vertebra. There was total loss of power in the lower extremities and loss of sensation below the umbilicus.

Bladder and rectum were both paralyzed. Cystitis, together with bedsores of a trophic nature, developed, and the patient died September 10th, having been admitted August 25th. The autopsy revealed a fracture of the tenth dorsal vertebra, greatly compressing and crushing the cord.

Injury to the *conus medullaris* causes paralysis of the bladder and rectum and anesthesia in the gluteal region. Such cases are not very common. The symptoms detailed and cases related are applicable only to total or nearly total transver e lesions, conditions in which the functions of the cord at the level of the injury are entirely abolished. It often happens, however, that the injury does not involve the entire thickness of the cord. In this latter case the symptoms present wide variations. Sensation may be greatly or very slightly affected, and all grades of paralysis may exist. A partial lesion in the mid-dorsal region may not involve the sensory conducting-fibers to any appreciable extent, and the lower centers, as those for the bladder and rectum, may be intact. Motion in such a case as

this would be interfered with to a moderate degree only, or more or less entirely lost.

We may have one lateral half of the cord interfered with, giving Brown-Séquard paralysis: motion lost on the side of the lesion, sensation on the opposite side. In the cases in which the lesion does not involve the entire thickness of the cord, the patellar reflex is as a rule greatly exaggerated, unless the lesion be in the lumbar enlargement, when, of course, the knee-jerk is lost, because the center is involved and the reflex arc is broken. In those cases in which the cord is entirely severed, even though the lesion is in the cervical or dorsal region, the patellar reflex, as Bastian has pointed out, is lost and we have a flaccid paralysis. A case recently under my care showed the curious combination of entire loss of motion and sensation in the lower extremities, with greatly exaggerated reflexes and ankle clonus. The only explanation of such symptoms that can be given is that the cord was involved in almost its entire thickness, having intact only a few white fiber-tracts, probably the direct cerebellar columns. It must be borne in mind that occasionally the nerve-roots only are involved, without any injury to the cord: the local nature of the symptoms renders the diagnosis easy, as a rule.

In considering the cases in which only moderate injury is done to the cord, a question of great interest arises, namely: To what extent may the cord be injured by blows, falls, and the like, which do not cause fracture or dislocation of the vertebræ? We may, I think, have three varieties of cord-injury resulting from external violence which has not been sufficiently great to cause any rupture of the bony parts: laceration to a moderate degree, compression from hemorrhage due to rupture of the spinal veins, and finally, a general disturbance of nutrition, without any immediate alteration of structure or marked symptoms, the condition known as concussion proper. The following case will illustrate the first variety, or moderate laceration without any fracture or dislocation of the vertebræ:

CASE V.—A female, aged twenty-two, on July 25th fell through a skylight to the floor beneath, a distance of fourteen feet. There was no loss of consc ousness and but little shock. Examination showed a bruised and somewhat tender spot in the lumbar region, but no evidence of fracture or dislocation.

The temperature was normal, as also were the pupillary reflexes. There was complete paralysis of the lower extremities and of the bladder and rectum. The deep and superficial reflexes, from the waist down, were abolished. There was anesthesia of the gluteal region and of nearly all the surface of the lower extremities. The patient has slowly improved, and at present, nearly six months after the injury, has recovered to some extent the use of her right leg. The left leg is still nearly powerless, and shows marked foot-drop, and only partial return of sensibility. The reflexes are very feeble.

The second variety of compression by intra-spinal hemorrhage without fracture is interesting, and has been confirmed by surgical operations for the relief of the pressure occasioned by the hemorrhage; the bleeding generally is found to come from the rupture of the spinal veins. The following case might perhaps be included in this category.

CASE VI.—A male, aged sixty-two, was crushed in an elevator. Several ribs were broken, but no distinct fracture of the vertebræ could be made out. There was no displacement of the vertebræ. There was almost total loss of motion in the lower extremities, with anesthesia extending to the crests of the ilia, and above this a very sharply-defined band of hyperesthesia. There was no elevation of temperature. The patellar reflex was abolished; the bladder was not paralyzed. Examination on the following day showed that the hyperesthesia had disappeared, and in a few days motion and sensation began to return and the patient was discharged cured at the expiration of two weeks. The deep reflexes had not returned when the patient left the hospital.

The third variety of injury to the cord, without fracture of the vertebræ, or any evidence of gross lesion, is that condition known as concussion of the spine. The limits of this paper do not permit any discussion of this interesting part of the general subject of injury to the cord. Ever since the appearance of Erichsen's notable paper, there have been bitter discussions in regard to the existence of such a condition. Unfortunately, the battle-grounds have been oftener in the courts than in the medical societies.

While a certain proportion of the cases of "railway spine" are fraudulent, or at least imaginary, and the symptoms stimulated by prospective "damages," there can be no doubt of the genuineness of many cases. Nor is the probable pathology hard to conceive. As we have seen, the cord may be injured severely by a blow or a fall that does not cause fracture or displacement of the vertebræ. Now, it would seem not improbable that a severe fall might seriously disturb the nutrition of certain parts of the cord, causing injury much less in degree than laceration or hemorrhage, which have already been considered.

As the result of a concussion, there might be sufficient injury done to the gray matter to initiate a degenerative process in the cellular structure, and, as a consequence, muscular weakness and atrophy in the parts depending for their innervation and trophic influence upon the cells in question.

Again, if the fiber tracts be even slightly injured, a myelitis may result and cause a more or less widespread secondary degeneration. Suppose an injury,

to the posterior part of the cord, by a fall, blow, or twist; the immediate effects of such an injury may not be at all marked, yet if there has been decided damage done to the fiber-tracts there will be an upward degeneration of the posterior columns, or the pathologic lesion of tabes dorsalis. The specimen shown of Case II. very beautifully illustrates this point. The injury to the cord was in the lumbar region, and the cervical cord shows most marked degeneration of the posterior colums, as can be seen from the section exhibited. This very marked degeneration has taken place in two months. In like manner we may have degeneration of the lateral, the direct cerebellar columns, etc.

It is, I think, quite possible that we have underestimated the importance of traumatism, in searching for some satisfactory etiology of the chronic system-degenerations or scleroses of the spinal cord. As a matter of fact, we have reports of cases pointing clearly to traumatism as their starting-point, and it is a common observation that an apparently trivial accident will often hasten and develop a case of incipient sclerosis.

The foregoing remarks sufficiently illustrate the nature of the changes of a secondary character that take place in the cord. As a result of these secondary degenerations, we have muscular atrophy, contractures, bedsores, cystitis, and like symptoms. Cystitis is especially troublesome and very commonly leads to secondary kidney-changes.

The diagnosis of these cases is not generally difficult, but, as Gray has suggested, it is always well to write out carefully all the symptoms, so that we may compare them with the tables given in the books and express the limits of the involvement of the cord in terms of the vertebræ.

The question of treatment in these cases of traumatic injury of the cord is an exceedingly difficult one to determine. As we know, we can expect little from medicine. Rest, counter-irritation, electricity, gold and silver salts, mercury, arsenic, and many other therapeutic agents are employed, but it is very questionable whether any of them influence in any degree the morbid processes. Undoubtedly, some cases do recover, but everything probably depends upon the degree of injury and the subsidence of the compression. The prognosis in those cases in which the cord is crushed and its whole substance destroyed is, if treated medically, absolutely hopeless. Such cases either die at once, or drag out a miserable existence through a few months and die of exhaustion from bedsores or secondary kidney-changes set up by the almost inevitable cystitis.

All we can do is to nourish the patient, to keep the bladder washed out, and to minimize as far as possible the evil effect of the bedsores, which nearly always occur, in spite of the most scrupulous care, and which, in most cases, must be regarded as trophic lesions. Such being the gloomy outlook in the medical treatment of these cases, we naturally turn to surgery.

It is out of place in this paper to discuss this part of the subject, but a few considerations as to the class of cases suitable for operation may be permitted. There is hardly any question about the propriety of operating when we have cases in which there are marked signs of compression, without evidence of total destruction of the cord. The main points to be regarded in making the differential diagnosis between partial and total destruction of the cord have already been considered. A considerable number of cases successfully operated upon attest the correctness of this position. If the compressing agency be removed early, the cord may recover in great part, but if operation is long delayed, secondary degeneration is likely to set in and interference to be rendered useless.

In those cases in which there is total destruction of the cord, most neurologists advise strongly against any operation as useless. It has always seemed to me that, in view of the fact that these cases practically always prove fatal under medical treatment, we should not advise against what would seem to be a natural surgical procedure. We have broken bone, crushing and compressing the cord, and the most natural thing would be to clear away the débris and give a chance to whatever bit of cord there might be left uninjured. Observations in a number of autopsies of cases that presented all the symptoms of complete crush of the cord have convinced me that it is rare to see the cord entirely destroyed by the traumatism, and in a considerable proportion of these cases there was distinct evidence that part of the damage was due to secondary inflammatory processes. Operative procedure offers not merely the best chance, but in nearly all of these cases the *only* chance, and if properly carried out does not materially add to the gravity of the prognosis, even if it accomplishes nothing. Abbe's brilliant work upon the cord, while as yet rather barren of results, is full of suggestion. As has been already noted, an operation, to be of any avail, must be done early. We should allow only time enough to make it certain that the symptoms are not due to shock or temporary interference with function. I know of no class of cases that more strongly appeal to me than these cases of injury to the cord, for I always feel instinctively that something ought to be done for them, and I am confident that the surgery of the future will make this possible.

The Gross Medical College Bulletin is the name of a new monthly publication emanating from Denver, Col., and edited by Dr. T. H. Hawkins and Dr. E. C. Hill.

PULMONARY ATELECTASIS AS A CAUSE OF ANEMIA.

BY ALBERT ABRAMS, M.D.,
OF SAN FRANCISCO, CALIFORNIA.

IN this paper I shall discuss anemia, not as a substantive, but as a symptomatic affection. I have referred elsewhere[1] to cases of anemia occurring in individuals, the examination of whose lungs showed insufficient distention or atelectasis. Since then, my observations have been supplemented by accurate blood-measurements, which enable me to assert positively that atelectasis of the lungs is a frequent factor in the etiology of anemia. Atelectasis, or collapse of the lung, is often encountered as a physiologic condition, and I have adverted to it in my *Manual of Clinical Diagnosis*[2] as follows:

"Remembering that the tidal or breathing volume of the air amounts to only 33 cubic inches, and the complemental air, which is the air taken into the lungs by forced breathing, in addition to the tidal volume, amounts to 100 cubic inches, and knowing that the average respiratory capacity of an adult is about 225 cubic inches, the conclusion is evident, that even in a state of health the lungs are imperfectly aërated, and in a condition of *physiological atelectasis*.

"My invariable custom before conducting an examination of the lungs is to have the patient make repeated forced inspirations. In this way I avoid many errors in auscultation and percussion."

I have particularized this matter for the reason that I have failed to find similar detailed reference to physiologic atelectasis in our text-books on diagnosis. I can recall a number of cases in which an examination of the lungs revealed dulness at one or both apices, and in which an unfavorable prognosis was given, in accordance with the physical examination. I can also testify with chagrin that these very cases, which I consider so unfavorable, continued well, despite my inauspicious prognostications. These errors in diagnosis are examples of similar errors made by other physicians, and which will continue to be made until pulmonary atelectasis is recognized as a physiologic condition. I have repeatedly demonstrated patients to my classes in physical diagnosis who showed not only circumscribed dulness of the apices or borders of the lungs, but even, in fact, dulness of an entire lung; and it was shown in these cases how, after repeated forced inspirations, dulness was supplanted by resonance. These cases were not recruited from bedridden individuals, in whom such a condition might be expected, but from ambulatory patients. There is no individual, however resonant his lungs on percussion, who cannot render them more resonant after repeated deep inspirations. If atelectasis is found as a physiologic condition in robust individuals, how much more frequent it must be in those individuals with incomplete thoracic development, who forego all hygienic influences which tend to promote proper respiratory activity.

The occurrence of anemia, with its concomitant symptoms in pulmonary atelectasis, is not accidental, but almost constant. The blood is a definite living tissue whose chemical composition is almost constant. By means of the blood the constituent elements of the body are furnished with the nutrient substances and the oxygen they require; both are derived from without, the former from the alimentary tract, the latter through the lungs. The entrance of oxygen into the blood is necessarily influenced by the vascular area exposed to the air, which in pulmonary atelectasis is, of course, diminished. The excretion of carbonic acid from the blood must for the same reason be interfered with. Then, again, the excretion of organic matter during expiration is interfered with, the accumulation of which in the blood conduces to auto-intoxication.

The symptom-complex of individuals with collapse of the lung, based on an analysis of twenty-five cases, is as follows: Hemoglobin (estimated with Fleischl's hemometer) is reduced to 50 per cent., or lower; the red blood-corpuscles are diminished in number. The reduction of hemoglobin and in the number of red blood-corpuscles is proportional to the area of lung collapsed.

Fatigue on exertion, shortness of breath, palpitation of the heart, loss of appetite, and constipation, are the usual subjective symptoms.

On inspection, diminished movements of the thorax are noted. Percussion of the lungs shows diminished resonance throughout. The apices may show dulness on percussion, and circumscribed areas of dulness are often found in the interscapular regions, particularly on the right side. The upper lobe of the left lung, adjacent to the manubrium sterni, is a frequent seat of dulness.

Auscultation shows on quiet respiration an absence of respiratory sounds over the dull areas, while over the entire lung the respiratory murmur is enfeebled. When the patient is instructed to take deep inspirations, atelectatic crepitation is heard. The diagnosis is usually easy; repeated forced inspirations cause a disappearance of the dulness, and a reappearance of respiratory sounds. All of my cases showed almost immediate improvement after the inhalation of relatively compressed air by means of the pneumatic cabinet. The improvement in pulmonary atelectasis was phenomenally rapid, and occurred in some of the cases after three or four sittings. The color of the patients improved, the

[1] "Report of 163 Cases Treated by the Pneumatic Cabinet," Pacific Medical Journal, September, 1891.

[2] Abrams: Manual of Clinical Diagnosis, 1891.

percentage of hemoglobin and the number of red corpuscles increased, and the subjective symptoms of anemia disappeared.

If relapses occurred, and these were not infrequent, they were attributed in the main to neglect of lung-gymnastics, and a return to former modes of life. In a few cases nasal obstruction led to relapses. In this connection reference must be made to investigations of Holbrook Curtis,[1] who demonstrated that all patients with nasal stenosis are anemic, and after removal of the obstruction the cases were cured. In cases in which nasal obstruction cannot be removed, the simple expedient of having the patient breathe through the mouth may be adopted.

Although I have used the pneumatic cabinet for the treatment of pulmonary atelectasis, I am thoroughly convinced that no special apparatus is required if the patient is properly taught to make repeated voluntary forced inspirations.

In anemia of pulmonary origin the therapeutic action of chalybeates may be hastened by inhalations of oxygen. Oxygen is as essential an element of hemoglobin as iron. Sufficient oxygen for all practical purposes may be taken into the lungs, provided no atelectasis is present, and forced inhalations will prove of great value in the treatment of anemia, even when not of pulmonary origin.

Oxygen is now commonly used as a therapeutic agent in many diseases. The oxygen of the blood is chemically united with the iron, and is not subject to the law of absorption, and in consequence the exchange of gases between the blood of the air-vesicles occurs almost exclusively through the agency of chemical processes, and therefore independently of the diffusion of gases.

When pure oxygen is respired, the blood does not take up more oxygen than when atmospheric air is respired. Inhalations of oxygen, nevertheless, do good, and this good is effected, to my mind, not because pure oxygen is inhaled, but in consequence of repeated forced inspirations opening up normally collapsed lung-areas, and thus exposing a greater quantity of blood to the inhaled oxygen. The cachexia of individuals who suffer from cardiac valvular lesions is due largely to stasis in the lungs, the turgid vessels compressing the air-vesicles. It can be shown that the blood of these individuals contains less hemoglobin than normal, and that the hemoglobin increases when the collapsed lung is opened by voluntary forced inspirations.

I know of no more simple means of relieving the dyspnea of uncompensated valvular lesions under certain circumstances than by the inhalation of compressed air, the object being to dilate the collapsed areas of lung.

[1] Journal of the American Medical Association, August 3, 1890.

The following conclusions may be formulated:

1. Physiologic atelectasis of the lung is a frequent condition.

2. It may be readily diagnosticated by the presence of circumscribed areas of lung-dulness, which disappear after repeated forced inspirations.

3. Physiologic atelectasis of the lung is frequently associated with anemia.

4. In all cases of anemia of obscure origin, examination for physiologic atelectasis of the lung should be made.

5. Anemia due to physiologic atelectasis may be cured by inflation of the lungs.

6. Forced voluntary inspirations are an excellent substitute for inhalations of pure oxygen, and are of great value in the treatment of anemia from whatever cause.

ORIGINAL LECTURE.

ESOPHAGEAL STRICTURE AND GASTROSTOMY.[1]

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, UNIVERSITY OF BUFFALO, N. Y.

THIS patient is a girl of eighteen upon whom, two or three years ago, I performed the operation of gastrostomy on account of esophageal stricture due to the swallowing of hot lye. At that time immediate operation was necessary, as the gradual contraction of the cicatricial tissue in the esophagus had progressed so far that even liquid nourishment could not be swallowed in quantities sufficient to support life. After a year or more I restored the patulousness of the esophagus by the electrolytic current and the passage of a sound, and then the opening into the stomach was closed. The most explicit directions were given as to the necessity of care in diet and of returning to the hospital to have the esophageal bougie passed often enough to prevent a return of the trouble. But, unfortunately, the girl is one of a considerable proportion of the population who are indifferent to the future and who lack perseverance. From sheer heedlessness she has twice allowed the esophagus to close, and twice we have dilated it again by means of sounds and the galvanic current. Every man who practises in a hospital has seen urethral strictures entirely overcome, has impressed on the patients as positively as he could the necessity of passing the sound occasionally to maintain the urethra in its restored patulousnenss, and yet has repeatedly seen such patients return with almost the original trouble, from neglect of the simple procedure of whose absolute necessity they had been warned.

This girl now returns with the request to have her stomach opened again, saying that she must work and cannot take time to go to a hospital or dispensary to have the bougie passed. She says, too, that she was more comfortable with the artificial opening in the stomach. While I may question her taste in the matter, I think that her own wishes, expressed positively and repeatedly, should be considered. I shall, therefore, reopen the stomach and allow her to return to the old *regimen;* and

[1] Delivered at the Buffalo General Hospital.

if, later, I can convince her of the propriety and desirability of keeping the esophagus patulous, and especially if she can be taught to pass the bougie herself, then it will be a simple matter to close the gastric fistula.

The operation in this case is an easy one. For years the stomach has been in contact with the abdominal wall and is firmly adherent to it. At the first operation of this sort, we have to open through the abdominal wall, find the stomach, draw it up to the wound and stitch it there, before opening into its cavity. Unless there is some emergency requiring haste, the completion of the operation is left until the next day, so as to allow peritoneal adhesions to form and thus prevent all possibility of leakage of chyme into the peritoneal cavity. In this case, the adhesions are already firm and nothing is required but an incision directly into the stomach and the insertion of the gastrostomy tube. We must distinguish between the words *gastrotomy* and *gastrostomy*. The former refers to an operation in which the stomach is opened and sewed up again immediately, as in removing a set of false teeth, a coin, or some other foreign body. By gastrostomy, we mean the establishment of a more or less permanent fistula. We have the same distinction between enterotomy and enterostomy.

The first time I operated to produce a gastric fistula was in the case of a woman with carcinoma of the esophagus, who was so weak that I was unwilling to give chloroform, and used cocaine—the first celiotomy ever done, at least in this country, under cocaine-anesthesia. Since then, I have repeated gastrostomy and have done two or three other celiotomies under cocaine. This girl is so hysterical that I prefer using chloroform in her case.

On the abdomen you see a scar, and in its center a star-like puckering which represents the original opening into the stomach. It is only necessary to cut through the scar, which bleeds very little, to reach the cavity of the stomach. The original operation has its little technicalities. The incision is made below and parallel with the left costal cartilages, beginning to the left of the linea alba; hemorrhage is controlled before opening the peritoneum and then the stomach is sought. Sometimes the colon presents, and I can imagine that the tenaculum might be hooked into it by mistake, but the difference between the two organs ought to be apparent. After drawing the stomach into the abdominal wound, it is held there by piercing it with a long, slender pin, like a hat-pin, which may be left *in situ* two days, and then the stomach-wall is at once sewed to the abdominal wall. For the second part of the operation, which, as I have told you, is usually postponed twenty-four hours or longer) no anesthetic, not even cocaine, is necessary, for the stomach is not provided with ordinary sensory nerves, and the incision occasions only a vague discomfort. This part of the operation may also be performed with the thermo-cautery. In gastrotomy for the removal of a foreign body, the stomach is drawn outside the abdomen and opened there so as to prevent the entrance of any of the stomach-contents into the peritoneum. The wound is then closed securely and the stomach dropped back, whereupon the abdominal wound is closed as in ovariotomy.

The wound here will be fitted with a tube having a shield like the collar of a stovepipe, to prevent its slipping into the stomach. It is to be held in place by a band about the body. The patient can wear a cork in the tube for the sake of cleanliness, and withdraw it whenever necessary to introduce food.

Two or three years ago Mr. Simons, of Guy's Hospital, devised a fairly practical way of introducing a tube into a constricted esophagus, to be retained for purposes of nutrition. His tube is analogous to the laryngeal tube of O'Dwyer, but, for anatomic reasons, it cannot be made of unyielding metal. You see here that it is a varnished silk and gum tube, funnel-shaped to prevent its slipping through the stricture into the stomach. It is worn for a few days, or weeks, until it becomes so far disintegrated as to necessitate removal. It is introduced by an obturator or universal handle, very much as the O'Dwyer tubes are inserted. A piece of strong silk ligature is attached, to facilitate removal. Probably no person, however enduring, would be able to have the silk hang from the mouth. Aside from the constant annoyance, it would be likely to be chewed off during eating, or unconsciously divided or swallowed during sleep. The thread is, therefore, drawn up through the pharynx and out of the nostril, and secured by a piece of adhesive plaster to the cheek. It may be necessary to remove such a tube after a day, or perhaps it may remain a month. It may be withdrawn and inspected and then reinserted. Solid food will not pass through such a tube, but strained broths, milk, porridge, etc., can be swallowed. The voluntary effort at swallowing is sufficient to carry the food to the point of stricture, and the presssure from above forces it down into the stomach. All such apparatus have their attendant disadvantages. Even a soft silk tube will cause more or less ulceration, and even dangerous hemorrhage may follow. The necessity for frequent removal of the tube is also a source of trouble and expense. The introduction of the tube involves additional danger. It is a simple thing to pass an esophageal probang in a healthy esophagus, but as soon as one reaches a stricture, the passage may become tortuous, or there may be ulceration on one side, and the instrument may be deflected from its proper course and may do serious damage. A London physician introduced one of these tubes into the esophagus of a patient of considerable influence in society, and sent him home, as he supposed, most satisfactorily ; but the patient died the next day, and at the autopsy it was found that the esophagus had been perforated and that the tube rested in the anterior mediastinum. That one fatal case did much to discourage London men from using this instrument. I have not yet seen the case that I thought just fitted for such treatment. I could use such an instrument in the case of this girl, but I could not trust her intelligence.

At clinic, eighteen days later. This patient, on whom you saw the operation of gastrostomy performed, is about the ward and is doing well in every way. I have brought her before you in order to show you the tube which she wears in the gastric fistula. It is an improvement on the one first introduced. There is an external shield with a broad flange, which prevents its slipping in, while an attached bandage keeps it from coming out. Inside the shield is a smaller tube, whose depth in the stomach is regulated by a set-screw which fastens it to the shield. The outer end is closed with a rubber cork, except when food is introduced, when the stomach-tube is connected with a funnel by a piece of rubber tubing.

CLINICAL MEMORANDA.

A CASE OF CHOLECYSTOTOMY, WITH RECOVERY AFTER REMOVAL OF GALL-STONES.

BY THOMAS G. MORTON, M.D.,
PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC; SURGEON TO THE PENNSYLVANIA HOSPITAL; AND TO THE ORTHOPEDIC HOSPITAL OF PHILADELPHIA, ETC.

MRS. X., of Yardleyville, Pa., aged fifty-eight years, for many years suffered with irregularly-timed attacks of pain in the right hypochondrium, which occasionally, also, shot into her shoulders, more especially the right. Otherwise she had been entirely healthy and without important medical history. She never was jaundiced.

On November 11, 1892, she was seized with one of her attacks, but this was of unusual violence and accompanied with marked prostration. Her temperature was variable, and fluctuated between 99° and 103°. The abdominal pain was intense, but the stools were normal and there was no jaundice.

I was summoned to a consultation with Drs. Joseph E. Smith and W. S. Gillam, of Yardley, Pa., November 18th, when I first saw the patient. At this time her temperature was 102° and she was suffering intensely. The pain was much aggravated by motion and by palpating the right hypochondrium. In this region was discovered a very large, somewhat globular mass, between which and the liver there was no line of percussion-resonance, but the dulness was continuous. The tumor was slightly movable toward the spine, but in no other direction. Fluctuation was not present, or could not be developed. The bowels were open and normal.

As her condition appeared to be threatening, and as it was stated that the tumor had been rapidly increasing in size, it was determined to make an exploratory incision over the tumor without further delay, and be guided, as to subsequent procedures, as circumstances might direct. Accordingly, a four-inch incision was made through the abdominal wall, in the right hypochondriac region, immediately over the most prominent portion of the tumor. When the peritoneum had been opened to the full length of the external wound, an intensely distended cyst presented itself to view and almost entirely filled the bottom of the incision. This cyst proved upon examination to be an enormously distended and thickened gall-bladder, in size and shape much resembling a large cocoanut. It was intensely congested and in spots appeared as if it were about to become gangrenous. Flakes of recent lymph appeared wherever it had come in contact with other parts. About an inch of very much attenuated border of the liver appeared in the upper portion of the wound; but the cyst ran under and far above this tongue. A finger was carried around the gall-bladder in all directions and it was found to be quite free from adhesions, save the recent flakes of lymph already spoken of.

It was now determined not to open the cyst-wall, nor to attempt to suture it into the wound, for fear that the contents—being under evident pressure and of unknown character—might leak out through the punctures before surrounding and protecting adhesions had formed. The peritoneum was accordingly sutured to the skin-margins of the wound all the way around the opening, and the wound-cavity thus formed stuffed lightly with gauze, it being observed that the distended gall-bladder, and in part the liver-substance, occupied and closed the opening into the peritoneal cavity, and formed the floor of the wound.

The subsequent course of the case was very gratifying. Her temperature fell to normal almost at once after the operation and she was entirely free from pain. No food was given for thirty-six hours, thirst being relieved by six-ounce hot-water enemata containing two drams of brandy, administered at frequent intervals. Subsequently, she was given two drams of the juice of slightly broiled beef, every two hours until the bowels moved, on the third day, after which ordinary diet was gradually resumed. The bowels were opened at this time by one-tenth-grain doses each of calomel and podophyllin, given every two hours, beginning on the second day.

The second stage of the operation was not performed until two days later. At the end of forty-eight hours the dressings were taken away and the gall-bladder was found now to be firmly anchored in the bottom of the wound by strong peritoneal adhesions, thus cutting off all access to the peritoneal cavity. Two silk stitches, with long ends for control, were then passed into the wall of the bladder, one at each side of the wound. As soon as this was done pus poured out in a little stream from each puncture—thus proving the wisdom of not having attempted suture of the viscus at the time of operation, for then it would have been almost impossible to have protected the peritoneum from infection by the discharges, either at that or a subsequent time, if that course had been followed.

After the controlling sutures had been passed, as above stated, the cyst, or gall bladder, was opened by a bistoury to the extent of two inches in a vertical direction between the sutures, traction upon which now held the opening into the bladder widely open and at the same time gave support to the walls when a finger was passed into the interior. The thin portion of the liver, above referred to was incised to the extent of half an inch in making this opening; bleeding from it was free for a few moments and then spontaneously ceased. When the finger was introduced it at once came upon a large gall-stone lying loose in the interior of the gall-bladder, surrounded by pus. When this was removed, another, almost as large, was encountered in the cystic duct. This was likewise removed with forceps, after having been dislodged by a teaspoon. Then another calculus could be felt further along the duct, and after it had been taken away a fourth was felt, at a distance of six inches from the external opening, encysted in the bladder-wall. Considerable difficulty was experienced in dislodging this stone from its deep and constricted position, but this was finally accomplished by means of a small, long-handled, ordinary teaspoon, and it could then be grasped by a long-handled volsellum guided by a finger. While the last two stones were being removed the woman complained bitterly that I was causing her just such "rheumatic" pains as she had been having in her stomach and shoulders for years. Besides the four large stones above mentioned there were also removed or washed out from the bottom of the cavity a very large number of smaller calculi weighing from a

fraction of a grain to twelve grains each. These smaller stones in the aggregate weighed about seventy grains. The dimensions were subsequently taken of the three larger stones, when dried—circumference four inches; another was three and one-quarter inches in circumference. The weight of the four larger stones was 815 grains, or 1 ounce, 5 drams, and 35 grains (52.8 grams).

The cavity was then washed out with recently boiled and cooled water, a large double drainage-tube put in, and a copious dressing of gauze gently packed about the opening.

On January 31, 1893, Dr. Gillam writes: "Mrs. X. began to improve immediately after the stones were removed. At no time since the operation did her temperature reach 100° and she had no bad symptoms. The discharge from the wound was almost pure bile, after the first few days, and the dressings would become saturated in three or four hours and have to be renewed. Once a day I syringed the wound out with a weak carbolized solution and there would be a number of calculi washed out; there were a few as large as a pea, but most of them were like grains of sand. These almost entirely disappeared after the first week." In another letter, he stated that the drainage-tube was taken out November 27th. "There had been a profuse discharge of bile and some pus, which at this period was much diminished."

In about two weeks after the operation the wound had closed so much that the syringe could not be introduced, but the bile continued to flow until December 23d, when it stopped. There was a very slight discharge of bile two days later—the 25th—but there has been none since. Previous to December 23d the bowels had been constipated and the stools light; but after that they became regular and natural in color.

The patient was allowed to sit up in a chair about December 15th, and on January 1st she came down stairs. There is still some tenderness about the wound but she has gained strength and says that now she "feels better than she has for fifteen years."

The treatment after the operation was very carefully conducted by Dr. Gillam. The cavity was daily washed out with antiseptic solutions and in three weeks nothing remained but a small fistula, through which large quantities of pure bile were discharged. This fistula narrowed and finally closed early in January, 1893. As soon as the biliary fistula closed the passages became darker in color and the bowels were moved naturally every day. Previously the stools had been light in color and only came away as the result of small doses of irritant purgatives.

Since the operation this woman has had entire freedom from the violent pains that with remissions she had exprienced for over twenty years. She states that she is thoroughly comfortable at all times and regards herself as perfectly recovered.

The Medical Association of Georgia.—The forty-fourth annual session will be in Americus, on April 19th, 20th, and 21st. *President*—A. A. Smith, M.D., of Hawkinsville. *Vice-Presidents*—Geo. J. Grimes, M.D., of Columbus, and Robert H. Taylor, M.D., of Griffin. *Secretary*—Dan H. Howell, M.D., of Atlanta. *Treasurer*—E. C. Goodrich, M.D., of Augusta.

A CASE OF ANEURISM OF THE AORTA, ASSOCIATED WITH INSUFFICIENCY OF THE AORTIC VALVES.

BY GEORGE C. SCHEMM, A.B., M.D.,
PHYSICIAN TO ST. MARY'S HOSPITAL, SAGINAW, MICH.

G. P., a male, aged forty-nine years, was admitted to St. Mary's Hospital January 3, 1893, seeking relief from a troublesome cough and hoarseness that had persisted for about three months. Otherwise he considered himself quite well, having been steadily at work up to the day of his entering the hospital. No very satisfactory history could be obtained, though, in a general way, it was ascertained that his health had always been good. The patient is at present free from pain; nor is there a history of pain during his illness. He is a well-built, robust man; his face is somewhat flushed, and the carotids can be plainly seen pulsating.

The laryngoscopic mirror shows the cause of the hoarseness to be paralysis of the left vocal band. During attempted phonation the left vocal band remains immovable in the so-called "cadaveric position," while the right advances normally to the median line.

On examining the chest we find the apex of the heart low down in the sixth intercostal space, quite an inch outside the mammary line. The impulse is heaving and extends over an unusually large area. The cardiac dulness is increased in proportion. The heart-sounds at the apex are normal, but over the aortic area a loud double murmur (systolic and diastolic) can be heard. This murmur is heard with even greater intensity along the left infra-clavicular region. Neither pulsation nor dulness can be detected over this area. When the patient assumes a recumbent position there is marked dyspnea and stridor. The right and left radial pulses are alike in time and character. The respiratory sounds are normal over both lungs.

When the larynx is grasped between the thumb and finger and elevated, a marked downward tug is felt with each heart-beat. No record was made of the relative size of the pupils.

From the physical signs in the chest the only conclusion to be drawn was that we had to do with a case of insufficiency of the aortic valves, with consequent hypertrophy of the left ventricle. This, however, was not sufficient to account for three important symptoms—the paralysis of the left vocal cord, the dyspnea in certain positions, and the tracheal tugging. Evidently there was pressure upon the trachea and upon the left recurrent laryngeal nerve, most probably, as it seemed, caused by an aneurism springing from the aorta.

From the time of the man's entrance into the hospital the condition remained about the same until the morning of February 16th, when he suddenly began spitting blood and in a few minutes dropped dead from hemorrhage.

At the autopsy only the chest-cavity was examined. On opening the chest the edges of the lungs were found overlapping the pericardial sac and presenting a glistening, congested hue. On incision, abundant frothy and bloody serum exuded. The heart was much larger than normal. The right ventricle was narrowed to a mere slit by the bulging walls of the left ventricle. The left ventricle was dilated and hypertrophied—the walls about an inch in thickness.

The valves of the heart were normal, with the exception of the aortic valves. These were studded with hard calcareous nodules, and were in parts rigid and shrunken. The aorta was much dilated, the walls irregularly thinned, and the intima covered with numerous calcareous plates. On the upper and posterior wall was an aperture about one-half inch in diameter, opening into a sac with soft, thin walls and about as large as a hen's egg. This sac was adherent to the left side of the trachea about an inch above the bifurcation, and at the point of adhesion the cartilage had become absorbed, the tissue softened and ulcerated, and perforation had taken place.

The points of special interest in the case are:

1. The presence of tracheal tugging.

2. The presence of aneurism of the aorta going on to perforation without physical signs.

3. The combination of aneurism with organic disease of the heart.

Much emphasis has recently been placed upon tracheal tugging as a diagnostic point in suspected aneurism of the aorta. McDonnell[1] describes the method of obtaining this sign as follows: "The patient is placed in the erect position and directed to close his mouth and elevate his chin to the fullest extent. The cricoid cartilage is then grasped between the finger and thumb, and by making gentle upward pressure the pulsation of the aorta will be distinctly felt transmitted through the trachea to the hand if dilatation or aneurism exist." From a study of twenty-five cases McDonnell draws the following conclusions:

1. Tracheal tugging does not occur in aneurisms that do not involve the transverse arch.

2. Tracheal tugging may be present when many other symptoms and physical signs are absent.

3. It is never present except in aneurism.

Dr. James Stewart[2] describes two cases in which this sign was present. Neither of them, however, came to an autopsy. He considers tracheal tugging a sign of the greatest value, and cites several writers whose experience is similar.

In the case I have described this sign was of especial diagnostic value, in the absence of dulness and pulsation over the seat of the aneurism.

The absence of physical signs of aneurism is easily explained by the course it took, springing from the posterior wall of the aorta, extending backward and upward and impinging upon the trachea. It did not touch the chest-walls, hence caused no physical signs. Nor is this a very unusual occurrence in aneurism of the transverse arch. It illustrates the remark of Broadbent (cited by Osler) that "the aneurism of physical signs springs from the ascending portion of the aorta; the aneurism of symptoms grows from the transverse arch."

Strümpell states that the association of aortic insufficiency and aortic aneurism is a not infrequent occurrence, and this we can easily understand, as both are the result of arterio-sclerosis.

The diagnosis is made from the diastolic murmur and the hypertrophied left ventricle, neither of which, in the opinion of most authorities, occurs in simple aneurism without disease of the aortic valves.

HOSPITAL NOTE.

A CASE OF UREMIA IN AN ALCOHOLIC PATIENT WITH VISCERAL COMPLICATIONS SUCCESSFULLY TREATED BY VENESECTION, DIAPHORESIS, AND NITROGLYCERIN.

Philadelphia Hospital.

Service of S. SOLIS-COHEN, M.D.

[Reported by W. E. Bruner, M.D., Resident Physician.]

J. S., an Austrian, thirty-six years old, was admitted to the Philadephia Hospital December 13, 1892. His family history was negative. He had had pneumonia when twenty years old. He confessed to gonorrhea, but not to syphilis. He had not had rheumatism, and had until recently considered himself in good health, although accustomed to have severe headache at times, and occasionally troubled with nausea. He has for years been drinking beer to excess, but not to drunkenness; and is short, fat, and heavy, with the typical flushed cheeks and bloated facies of a beer-drinker, even after edema elsewhere has passed away.

About eight months ago he was seized with severe pain in the lumbar region, which has gradually decreased until now it is only slight. For four or five months he has been obliged to pass urine several times at night. The urine is dark in color and small in quantity; micturition is attended with burning. For four months there has been shortness of breath, and for two or three months slight impairment of vision—in fact, the man says he was completely blind three weeks ago for a short time. Abdomen and feet began to swell about three weeks before admission.

On admission the patient was quite dyspneic, but not cyanotic. He was completely "water-logged"; the legs were markedly edematous, as were also the hands, arms, chest and abdominal walls, face, and conjunctivæ. Ascites was present to a considerable degree, and râles of edema were heard posteriorly throughout both lungs. The heart's action was feeble; percussion was not satisfactory, owing to the great amount of fat and the edema of the chest-wall. Auscultation of the heart was much interfered with by the loudness of the transmitted tracheal breathing. It revealed feeble sounds, as in dilatation, and with difficulty a mitral systolic murmur could be detected; the second sound was not accentuated. The urine, of which but a few ounces were passed, had a specific gravity of 1021, and was laden with albumin, which made more than two-thirds by bulk when the urine was boiled and then allowed to stand for twenty-four hours. Granular and broad hyaline casts were abundant. Ophthalmoscopic examination revealed a marked degree of albuminuric retinitis.

The man was placed at once upon cardiant diuretics: infusion of digitalis, with spirit of nitrous ether, supplemented after two days by sparteine sulphate and caffeine in small, frequently-repeated doses. Compound jalap powder was freely administered, and hot-air baths, aided at first by small doses of pilocarpine, were tried, but without inducing perspiration. The diet was restricted to milk. The mental condition was marked by stupor and irritability, and it was extremely difficult to get the man to take food or medicine.

On the 16th he had a general convulsion. When seen a few minutes later, his face was slightly cyanosed, the breathing was stertorous, the pupils were widely dilated, and head and eyes were turned to the left. Consciousness was completely lost. The vascular tension, as appreciable at the radials, was very high. Unfortunately the man was so restless that his temperature could not be taken. Three drops of croton oil were given at once, and twenty-four ounces of very black blood were withdrawn from the arm. Just as his arm was being bandaged he had a second and terrific convulsion; after the control of which, by inhalations of chloroform, the vein was at once reopened, and an additional half-pint of blood abstracted. The man then became wildly delirious. The lungs were filled with fluid, giving rise to moist râles; but, in spite of this fact, pilocarpine hydrochlorate, gr. ⅛, with sparteine sulphate, gr. ½, was given hypodermatically, and the steam-bath was started. The pilocarpine was repeated in an hour, with sparteine sulphate, gr. ¼, and the steam-bath was continued for three and one-half hours, with, however, but slight effect. Nitroglycerin (1 per cent. solution), gtt. 2, sparteine sulphate, gr. ⅛, and spirit of nitrous ether, fl ʒj, were given every hour during the afternoon and every two hours throughout the night.

On the following morning the patient was perfectly rational and very comfortable. The heart was acting more steadily, more strongly and less rapidly; the murmur was more readily detected, and the second sound was clearer. Hot-air and, later, steam-baths were given daily, aided by pilocarpine, gr. ¼ subcutaneously, or gr. ½ by the mouth; but it was several days before any marked effect appeared, when very free sweating took place.

On January 2d the patient was not so well. It had been decided to modify the treatment by giving alkaline diuretics with the sparteine and nitro-glycerin; but for several days he had been refusing to take his medicine, so that he got only what could be given hypodermatically, together with the baths. Urgent symptoms, however, had been absent. He was very nervous on this afternoon. His muscles were twitching and his hands jerking; his pupils were somewhat dilated, and he seemed on the verge of another convulsion. After a preliminary inhalation of amyl nitrite, croton oil was again administered, with pilocarpine and the hot-air bath; after which nitro-glycerin (gtt. 1 of a 1 per cent. solution) was given at first every half-hour, and then every hour.

On the following morning he was much better, and as he had considerable ascites it was decided to remove the fluid, and thus relieve the kidneys of that much extra work. Although some authorities advise against abdominal paracentesis under such circumstances, one hundred and ten (110) ounces of fluid were withdrawn, with no evil effect whatever, but with decidedly beneficial results. When the fluid had been removed, percussion in the right hypochondrium indicated smooth enlargement of the liver to a moderate degree.

Despite a severe attack of acute bronchitis, and later an attack of pleurisy, the patient has continued to improve. The edema has almost entirely disappeared, and the amount of urine in the twenty-four hours has increased to ninety ounces. Tested by heat, it contains about one-third its bulk of albumin. On several occasions the edema has rather rapidly increased; but pilocarpine and the hot-air bath, with the free administration of nitro-glycerin, in addition to his regular treatment by diuretics and cathartics, relieved the urgent symptoms. An attack of tachycardia, with a pulse of 170 per minute, was relieved apparently by strychnine sulphate hypodermatically. An asthmatoid attack was relieved by wet-cupping of the chest and hypodermatic injection of strychnine; on several occasions since there have been paroxysms of rapid breathing believed to be largely hysterical.

Present treatment consists of regulated diet, warmth, sparteine, caffeine, and nitro-glycerin, in alternation with Basham's mixture of iron and ammonium acetate, and purgation as necessary.

The noteworthy points in the case, as impressed upon the observer who saw it from hour to hour, and could compare its progress with that of other cases more or less similar in certain respects, are the prompt relief afforded by venesection in the first convulsion; the effect of frequently-repeated doses of nitro-glycerin in averting a second convulsion; the excellent result of abdominal tapping; the superiority of a combination of sparteine and caffeine in this instance to digitalis as a cardiant diuretic; the superior efficiency of diuretic mixtures containing nitrous ether over the same drugs unaided; the determination of the pilocarpine result to the skin and not to the lungs, notwithstanding the apparent counter-indication of pulmonary edema. Although caffeine was discontinued for a time during the period of cerebral manifestations, it is not believed that these can be ascribed to that drug. Its favorable influence since would seem to negative such a supposition. Of any single measure, venesection was the most useful at the moment.

MEDICAL PROGRESS.

A New Method of Rapidly Removing the Uterus.—At a recent meeting of the Kansas City Academy of Medicine, Dr. Emory Lanphear described a new method of abdominal hysterectomy. The abdomen and vagina having been carefully sterilized, an incision is made in the median line, terminating as close to the pubes as possible. The uterus, with one tube and ovary, is drawn to one side and a clamp is applied to the broad ligament, which is securely ligated half an inch beyond and cut through between the two. The procedure is repeated upon the opposite side. The uterus can now be lifted up into the wound and be easily separated from bladder and rectum. The incisions are carried anteriorly and posteriorly into the vagina, when the clamp of Kelly or that of Polk is introduced through the vagina and applied to the broad ligament as closely as possible to the uterus, and the opposite side is treated similarly, when the uterus is quickly cut away with curved scissors. The pelvis is irrigated and the abdominal wound closed, and drainage through the vagina provided for, as in cases of vaginal hysterectomy. The clamps are removed at the expiration of forty-eight hours. The operation can be performed in twenty-five or thirty minutes, and much more easily than vaginal hysterectomy with clamps. It is thought not necessary

to unite the bladder to the rectum, as union takes place just as quickly without sutures as with them.

Successful Operation for Incised Wound of the Heart.—MARKS (*Medical Fortnightly*, iii, 2, p. 44) has reported the case of a colored man, nineteen years old, who received a stab-wound of the left side of the chest and of the right arm. There was no vomiting of blood, and the urine presented no abnormality. With antiseptic precautions, the wound, which was situated over the ninth costal cartilage, to the inner side of the mammary line, and was an inch in length and directed transversely across the chest, was enlarged toward the median line for a distance of four inches, and the ninth and tenth cartilages, for a distance of an inch and a half, were removed. The pleura was found to have been perforated and air rushed in and out with the respiratory movements. The pleural cavity was filled with blood. The pericardium was also found to have been incised, and the wall of the heart contained an opening sufficiently large to admit about half an inch of the tip of the finger. The cavity was packed with gauze, the man was put to bed and hot bottles were applied. For about four days there was some acceleration of pulse and respiration and some elevation of temperature. Thereafter recovery was progressive. The patient arose from bed and walked about ten days after the reception of the injury, and was dismissed nine days later.

Abuse of the Milk-diet.—LECORCHÉ and TALAMON (*La Médecine Moderne; Wiener medizinische Presse*, 1893, No. 5, p. 180) call attention to the fact that, although milk is a perfect food, at least a gallon would have to be taken in the course of twenty-four hours in order to furnish a sufficient amount of fat, albumin, and carbohydrates. Few persons are able to take such large quantities for any length of time. A milk-diet may suffice for a person in bed, but it will not for an active person. The larger number of albuminurics are able to be about and a milk-diet must be employed as a medicament. Besides, it is not necessary that a milk-diet be persisted in in the remissions of the inflammatory process in the kidneys. When once the acute irritation has been allayed by means of a milk-diet and the establishment of polyuria has removed all danger of the accumulation of excrementitious matters in the blood, the continuance of a milk-diet cannot be expected to dissipate entirely the presence of albumin in the urine. A milk-diet is thus indicated in cases of acute nephritis, and during acute exacerbations of a chronic nephritis. It not only does no good, but it really does harm in cases in which the urine contains a minimal amount of albumin and the blood an excess of uric acid, perhaps in association with gout or in the train of acute infectious diseases.

Symphysiotomy in a Male.—ALBARRAN (*Le Mercredi Médical*, 1893, No. 4, p. 37) has reported the case of a man thirty-one years old, in which symphysiotomy was performed to facilitate the removal of a large recurrent epithelioma of the interior of the bladder. An incision was made in the middle line from about three fingers' breadth above the pubic joint to within a third of an inch of the root of the penis, from which diverged two other incisions, each about a third of an inch long, like the arms of an inverted Y. The tissues about the articulation were dissected away, the anterior wall of the bladder was protected from injury, and the joint was opened by means of a bistoury supplemented by a chisel and mallet. By flexing the thighs it was with gentle efforts possible to separate the pubic bones a distance of a little more than an inch and a half. When the bladder was opened it was found that there were two growths in the aggregate of the size of a mandarin. These, together with a trapezoidal area of the wall of the bladder, 2½ by 1½ inches, were removed. The bladder was closed by a deep layer of catgut sutures and a superficial layer of Lembert silk sutures. Hemorrhage from a plexus of veins necessitated a packing with gauze. The subsequent course of the case was entirely satisfactory. On the second day the packing was removed. On the eighth day a small amount of urine was found on the dressing. The small fistula closed after some time and the wound finally cicatrized perfectly. Four months after the operation the condition of the patient was in all respects excellent.

The Practitioner.

To Deodorize Iodoform, Creasote, and Guaiacol.—The odor of iodoform, creasote, or guaiacol upon the hands can be overcome by washing with linseed meal. Articles having an odor of iodoform may be washed in tar-water to which oil of wintergreen has been added. The taste of pills of creasote can be disguised by means of a little powdered coffee. The odor of iodoform or guaiacol in rooms can be dissipated by burning coffee. —*Deutsche medizinal Zeitg.; Monatsh. f. prakt. Dermatol.*, xvi, 4.

MILK-STERILIZATION.

IN the year 1891, 5488 deaths occurred in the city of Philadelphia among children under one year of age. Of this number, 1000 died from cholera infantum during the three summer months; 1400 died from inanition and marasmus, and 700 more from convulsions.

Cholera infantum is mostly prevalent in hand-fed infants. In a careful study, ARNSTEIN shows the disease to be directly due to fermenting and decomposed milk. BOOKER has found the bacillus lactis aërogenes and the bacillus coli commune present in the stools of cases of cholera infantum, but not in the feces of healthy hand-fed children.

Many of the deaths attributed to convulsions and inanition are also probably due to the toxic influences of germs ingested with the food.

When we consider the manner in which milk is treated before it reaches the consumer, as well as the various contaminations to which it is subjected in its transit from the udder of the cow to the table, we should hesitate long and debate well, before using it in its crude state as a food.

Often the animals themselves are diseased. Besides, the dairyman may be unclean; the receptacles may contain hosts of germs; and after the milk leaves the farm, it is often carted about in filthy wagons, exposed to the dust of the streets, or dispensed from the counter of a badly kept shop. Under these circumstances there is but little chance for milk to retain its purity.

Ten per cent. of the milk examined by the city milk-inspector during the months of July and August, 1891, was condemned because of adulteration and dilution; but the chief source of danger, the disease-producing impurities, are beyond the ken of the lactometer.

Various sterilizers have been devised to render milk sterile; but when milk has become infected with noxious germs, only such a degree of sterilization will prove effective as will interfere seriously with the digestibility of the fluid.

When the spores of the butyric-acid bacillus are present, seven hours of continued boiling are necessary for their destruction. Pasteurization (*i. e.*, the heating of milk to a temperature of from 130° F. to 150° F. for ten minutes) only facilitates the germination of these microbes. Boiling destroys the solubility of the lime-salts, in the absence of which the child's stomach cannot digest the milk.

According to the standard of SOXHLET, milk intended as food for children should contain the normal constituents; and after it has been heated in a steam-chest for three-quarters of an hour, at a temperature of 212° F., it should remain sterile in a temperature of 95° F. for one month. It is only possible to obtain such milk when the methods in vogue in bacteriologic laboratories are carried out at the dairy-farm. Milk should be received from the healthy cow in sterile glass jars, which, with their contents, are placed in steam sterilizers and heated for ten or twenty minutes at a temperature of 160° F., and transported directly to the consumer.

Should the milk then sour in a shorter time than usual some detail must have been omitted, and the inspector will be called upon to make an investigation, as he now does in the case of adulterated milk. For the present, hospitals, dispensaries, and physicians should aim to control the source of milk-supply for their small patients, especially during the summer months, and endeavor to provide families with pure milk, properly sterilized.

If this is done generally, a great lessening in the death-rate among infants must result. Statistics show that this summer-mortality is not confined to any one section of the city, and that it is as high among the rich as among the poor.

To summarize: Sterilization of milk, to be effective without causing chemical changes, must be practised directly after the fluid has been obtained; care must be exercised in handling and transportation, so as to prevent contamination; warming the milk, as is now ordinarily done, will only hasten and aid germination of organisms present.

THE AMBLYOPIA OF DIABETICS.

MAN is a credulous being, and physicians are but men. It is much less troublesome to accept unquestioned the statements of one's predecessors than to go out of one's way to confirm their accuracy or demonstrate their fallacy. This spirit is responsible for the perpetuation of many mistakes of observation and of reasoning, and for the failure to establish many a truth. Thus, it has been believed that pulmonary tuberculosis does not develop in those that have valvular lesions of the heart, and especially mitral incompetency, or that have carcinoma, or that have emphysema of the lungs. These various illusions have, one by one, been dissipated by the light of modern investigation and research, leaving behind the element of truth out of which they were conjured. The dictum that the development of cataract is a common complication of diabetes mellitus has long been transmitted from teacher to pupil, and has received general acceptance. MAUTHNER (*Internationale klinische Rundschau*, vii, 6, 7), whose opportunities for observation at the Vienna Klinik have been unusually large, takes pains to point out that this association, far from being common, is extremely rare. His observations were not confined to his own ophthalmic practice, but included a study of a large number of diabetic subjects at Carlsbad. In most of the cases in which defects of vision were found these could be as readily attributed to concomitant conditions, such as age, impaired nutrition, and other intrinsic influences. The number of cases of diabetes mellitus in which cataract exists will, at best, be found to be exceedingly small. It is pointed out that the peripheral striation of the lens sometimes found in diabetics, and especially in the inferior median quadrant, is quite common, and becomes progressively more frequent in individuals that have passed the fiftieth year of life.

Among the influences that might be considered as favorable to the development of cataract are: The displacement of water in the fluids and tissues of the body by the presence of sugar; a diminution in the resistance of the walls of the bloodvessels as a result of the disturbance of the general nutrition; the development, as a result of the pathologic metabolism, of toxic substances that give rise to inflammation and degeneration; the marked marasmus; complicating or intercurrent affections. If the ocular changes were due to the loss of water, they should likewise occur in simple polyuria. It is more than doubtful that opacities of the lens result from the presence of sugar, for there is evidence that the lens normally contains sugar. The development of cataract in an elderly person whose urine contains sugar, does not constitute sufficient ground on which to make the glycosuria responsible for the loss of transparency of the lens, for it is known that in the large majority of cases of senile cataract the urine does not contain sugar. The conclusion is reached that the presence of sugar in the fluids of the eye does not lead to any disease of the organ of vision, and especially not to the development of cataract. In a small percentage of cases of diabetes mellitus, however, the excessive elimination of sugar and of water does lead to the development of cataract.

Vision may also suffer in cases of diabetes in consequence of the occurrence of hemorrhage as a result of the lowered resistance of the walls of the bloodvessels in the train of the nutritive disturbance. The hemorrhage may involve the intra-ocular apparatus; retina, choroid, vitreous, conjunctiva; or intra-cranial structures: optic radiation, nucleus of the optic nerve, of the motor, sensory (and trophic) nerves of the eye.

EDITORIAL COMMENTS.

Professional Abuses.—An eminent physician sends us a letter from which we reproduce some extracts:

"I know of some practitioners who advertise in the daily press; of others who are commercially connected with drug firms, and who require their patients to take their prescriptions to certain drug-stores; and still others who are furnished with offices, free of rent charges, by proprietors of drug-stores, in lieu of the prescription trade of such physicians. The professional gentlemen referred to sneer at medical ethics so long as their private interests are at stake. And as a result of this humiliating state of affairs, our city, if not the whole State, is infested with quacks, to suppress which there exists apparently no law; and, *pari passu* with this growing evil in itself, the regular profession, as a rule, walks arm-in-arm with quackery and lives royally on the general spoils, on the credulity of a patient public, of a suffering humanity, the victim ever of impostors on the one hand and of commercial regular physicians on the other."

Our correspondent proposed to prominent members of the local medical society to introduce a resolution whereby such offenders should be expelled from the society. He says:

"I was told by these gentlemen that this step would be a most unwise one; that it would be harmful to my personal interests, and that if brought before the society the resolution would be *downed* and sat upon! Indeed, some of these physicians have not been able to suppress their indignation, and have candidly or otherwise advised me not to introduce any such resolution."

Our correspondent proposes to go straight on in openly and persistently opposing such abuses, and we trust he will do so. The very men that find themselves reduced to such disgraces are often they who will thank the reformer they pretend to vilify for putting things to rights. Medical practice cannot permanently be reduced to such a basis, but the longer the degradation continues the more difficult it is to get back upon the everlasting basis.

Action of the New York Academy of Medicine as to Croton-Water Contamination.—Again the New York Academy of Medicine has performed a double duty to the public and to the medical profession. Its action is most excellent in condemning the proposal to give a man without the least training or knowledge of sanitary science, unlimited power to expend two or three millions of the public money in buying property and regulating the water-supply of the city. A committee of the Academy was named to go to Albany and to represent the views of the Academy against the pending bill.

But in setting an example to the medical profession lies the chief merit. Every local and every general medical meeting or society should not fail to follow the example set, and to express its views with dignity but with the most absolute clearness upon questions pertaining to the public health. Medicine is henceforth largely preventive in function. The cure of disease is no longer the physician's sole duty. Nothing will more speedily and certainly raise the profession to the position of public honor and power it should occupy than this decided interest and influence in all questions of public sanitation. The interest it has, but it is not exercised, because it has not spoken as a body; the power it may have—and it cannot help being a power for good—if it will awaken to what is at once its duty and its opportunity.

Further Note as to H_2O_2.—THE MEDICAL NEWS is always glad to learn, and if in error, to admit it. Since our recent remarks on hydrogen dioxid we have learned that the reason of the bursting of a certain lot of bottles made by one firm whose product, as analyzed by Dr. Leffmann, was found up to the claim of volume-strength, was not spontaneous liberation of O on account of excessive charging, as we had supposed, but from impurity from rubber stoppers, causing decomposition and liberation of O under pressure. This being now avoided by the use of corks, it appears that a solution of 15 volumes can be made that will for a reasonable time preserve its strength, if not contaminated by impurities and not subjected to mechanical agitation. Nevertheless, a 10 or 12 volume solution is more stable, and the strength more than ample for all purposes. The objection to highly acid solutions remains just as we stated it. These do no good, and in the throats of children do much harm. We desire, while on the subject, to emphasize the value of the internal use of H_2O_2 in pneumonia, phthisis, diabetes, gout, whooping-cough, and anemia.

Limit Papers to Ten Minutes.—The New York Academy of Medicine, and especially the section on Pediatrics, has found it an excellent plan to limit the time of reading of papers in medical societies to ten minutes. In large and crowded meetings the long sessions consequent upon thirty or forty-five minute papers become wearisome, and interest is bound to flag. By begining without excuses or preambles, by condensing the substance of the offering, and by ending when done, few or no papers would suffer by limitation to a ten-minute presentation. Explanations, notes, and details may, if desired, be printed, but busy men want the essence of the matter promptly and clearly. But whether ten or fifteen, or even twenty minutes, be allowed, let the rule never be broken to pass no vote to give a reader more time. If given to one for the sake of courtesy, it must be to others—with the result we all know!

Venesection.—An attentive reader of clinical reports and lectures must be impressed with the fact that the therapeutic pendulum is rapidly swinging toward a more frequent resort to bloodletting. Venesection is not practised indiscriminately or without sufficient indication; but its field of usefulness is being discovered and defined. The revival of humoral pathology has doubtless something to do with this, as one who might hesitate to abstract twenty or forty ounces of nutritive fluid, is not afraid to relieve his patient of that quantity of a poisoned serum. In uremia and in puerperal eclampsia, as well as in certain cases of pneumonia, the practice is rational.

Importation of Infected Rags.—Whether or not the motive of those in New York arousing the controversy as to the importation of foul rags from Europe sprang from commercial rivalry, the fact remains that, if the samples of rags given Dr. Gibier to examine were "genuine," there is a most decided danger of the importation of infectious diseases by means of the rags. The Government at Washington now having legal power in all such matters, we may hope that this danger may be carefully looked after, and proper preventive measures instituted.

The Protective Tariff and the Profession.—A contemporary journal would not have the tariff on microscopes, surgical instruments, medical books, etc., *too* high, but just high enough to give us "prosperous instrument-makers." Bosh! The profession exists to alleviate the physical sufferings of mankind. Every unnecessary increase of price of the physicians' tools makes the service so much more expensive either to the physician or to his patient. This result is against good morals and good medicine.

The Consolidation of Medical Colleges, proposed in Chicago, is also urged by the profession in Cincinnati. Such

movements are as inevitable as centralization of power in governments and of capital in commerce. It is indeed strange that the multiplication of medical colleges has been permitted to reach the outrageous degree today existing. If professors had not been allowed to own and use the colleges as money-making tools it could never have reached the present extreme.

England's Drink-Bill, for the year 1892, though nearly two millions of dollars less than in 1891, reached the preposterous sum of over $720,000,000, and it is probable that over half this amount was wasted by the working classes. What a terrible factor such an abuse is in the production of disease and death, is as much beyond question as it is beyond estimation.

The Salaries of Medical Professors, attached to the chairs of medicine, surgery and obstetrics in the Universities of Edinburgh and Glasgow are $3000. It is now proposed to reduce the corresponding salaries at Aberdeen University to the same figures. The men occupying these chairs are allowed to practise. The salaries in other departments are higher, but practice is forbidden.

Increase of Mortality from Carcinoma.—The proportion of total deaths due to carcinoma in England shows a steady increase. In 1838 it was 1 : 140; in 1850 it was 1 : 74; in 1860, 1 : 62; in 1870, 1 : to 54; in 1880, 1 : 40; and in 1890 about 1: 28. In Scotland, and, indeed, all over the civilized world, a similar rate of increase is shown by statistical returns.

Legacies to Physicians are not allowed according to the French law, if devised during the illness for which the patient is treated. It has, however, been lately decided that, though the attending physician is thus debarred, the consulting physician is not so forbidden. If the attendant is a possible murderer, why is the consultant not such also?

SELECTIONS.

SANITARY SUPERVISION OF SCHOOLS.

THE Local Government Board of England has recently issued a circular, which has been indorsed by the Massachusetts State Board of Health, and which may, therefore, be considered as authority and representative of the work of boards of health in this direction. The following are extracts from it:

"1. The diseases for which schools may be closed or children excluded are such as cause infection from person to person—scarlet-fever, measles, diphtheria, whooping-cough, smallpox, and rötheln, in order of relative frequency. More rarely the same question arises as to enteric fever and diarrheal diseases, which spread mainly by agency of local conditions—viz., infected school water-closets and outhouses.

"2. A universal principle is, that all children infected are excluded, however light the infection may be to others.

"3. As to mumps and skin diseases, school interests are to be considered more than in the other affections mentioned; but if these should spread by allowing children to go to school, the loss to children and school would be greater than to exclude the infected.

"4. Closure of schools is a grave step for sanitary authorities to take, and seldom should be undertaken except in an actual epidemic, nor then as a matter of routine nor unless there is a clear prospect of preventing the propagation of disease not to be attained by any other means.

"To decide, the fact of many pupils affected is not a reason; but if in a large majority of families the first case be a pupil, and especially if among families far apart and attending the same school, school should be closed, and if the infected cases can be *proved* to have attended the school.

"5. The medical officer should promptly notify the teacher of an infected pupil, and it should be kept from school the length of time the medical officer specifies. School officers should *promptly* notify health authorities of cases of contagious disease, no matter what *name* is used for the disease. Such officers during an epidemic should note any symptoms, such as shivering, headache, languor (especially if sudden), vomiting, rashes, sore-throat. During scarlet fever or diphtheria epidemics, any sore-throat is suspicious, and pupils should be excluded until safe assurance is given by a physician.

"6. Commonly the failure to stop the spread of an epidemic, especially among pupils, shows continued attendance of unrecognized mild cases, and school may have to be closed.

"7. A matter of importance in deciding as to closure is the opportunity for intercommunication of pupils outside the school. In small hamlets this is slight. In some sections of cities, as in tenement districts, more harm than good may be done by closing.

"8. All notices of proposed closure of schools should be sent to school managers in writing, the reasons given, and time of closure specified and made as short as possible, and a second notice given before the time for the expiration of the first, if closure is to be continued beyond the time specified in the first notice."—*The Sanitarian.*

MEDICINE AS A CAREER.

DR. J. S. BILLINGS, in a recent article on "Medicine as a Career,"[1] arranges the preparatory years of one who would fit himself for the medical life, as follows:

"My young friend whose attention I wish to direct to medicine as a career will have spent five years at a good intermediate school as a preliminary to entering the university, which he does when he is about seventeen years old. He has spent three or four years at the university, four years at the medical school, one and one-half years in the hospital, and two years in travel and special studies. When, therefore, he is ready to begin work he will be about twenty-eight years old, and his education, living, books, etc., will have cost about eight thousand dollars from the time that he entered the university. It can be done for less, but this is a fair average estimate."

If this imaginary young friend went to Harvard, he would be more nearly nineteen than seventeen on entering the undergraduate department; he would be about twenty-three on entering the Medical School

[1] Forum, February, 1893.

with an A.B. degree; he would be twenty-seven when he secured his M.D. degree; and if he spent eighteen months in a hospital and two years in travel and special studies, he would be fully thirty years of age when ready to begin the practice of an arduous profession, the first years of which are apt to be years of patient drudgery. For turning such years to profitable account, the hopefulness, the enthusiasm, the elasticity of youth are most essential. But at the age of thirty, for most men, the sun is already high above the horizon, the dew is off the grass, and the first freshness has gone from the morning air.—*Boston Med. and Surg. Journal.*

"POLITICS."

THE Academy has done more than merely throw the weight of its influence on the side of the advocates of national control of quarantine methods; it has asserted the principle that a scientific body owes the country active service as well as advice whenever its scientific knowledge may help avert a common danger or advance the common welfare. We say this without the slightest intention of committing the *Journal* to participation in the ostrich-like feeling of security that a national quarantine administration, even the best that can be devised, will prove all-powerful for the preservation of the public health.

For the Academy to degrade itself by adopting the "politics" of the slums or pursuing the methods of the corrupt lobbyist would surely be bad; but for it to refrain from exerting its power to the utmost in the cause of public safety would be far worse. If the most influential medical organization in the country refuses to advocate measures of great importance to the whole nation, for fear of becoming involved in "politics," that organization is disgraced in the eyes of all loyal citizens. The Academy cannot avoid taking part in "politics" in its higher meaning, and, if it does its duty, need not fear contamination from the baser sort of "politics."—*The New York Medical Journal.*

CORRESPONDENCE.

VENESECTION IN RIGIDITY OF THE OS UTERI AND IN ALLIED CONDITIONS THAT MAY RETARD LABOR.

To the Editor of THE MEDICAL NEWS,

SIR: THE MEDICAL NEWS of December 10, 1892, p. 656, and of January 14, 1893, p. 55, contains articles written respectively by Dr. Edward P. Davis and by Dr. J. J. Lamadrid on the treatment of rigidity of the os uteri in labor, in which Dr. Davis recommends surgical interference by incision of the os, and Dr. Lamadrid dilatation by mechanical means.

I have seen labor apparently advanced and terminated naturally by means of the fingers used as dilators; but, if rigidity still persisted, I have as often resorted to bloodletting, with such favorable results that I have, so far, had no occasion to incise the os.

On April 24th, at 3 A.M., I saw a primipara, twenty-two years old, well developed, and of full habit. The os was not dilated sufficiently to admit the index-finger. As she had slept very little during the night and the pains continued with no apparent progress, I gave her at 7 A.M. a dose of morphine, from the effects of which she rested at intervals for several hours, after which the pains became stronger and more regular. Still the os remained rigid and undilated until 3 P.M., when I bled her from the arm until she complained of faintness. Shortly after returning to bed her pains became more frequent and stronger; the os softened and began to dilate, and at 5 P.M. the child was born. There was no laceration of the womb or perineum, and mother and child did well.

On January 20th, at 7 P.M., I saw in consultation a primipara, thirty years old. Labor had commenced at 3 or 4 A.M. I found the os dilated about three-fourths of an inch; both its external and internal parts were hard and unyielding to the touch. Her pains were mitigated by chloroform, which she had been allowed to inhale for several hours. I proposed venesection, and as soon as she recovered from the effects of the chloroform sufficiently to sit up she was freely bled from the arm. The pains soon came on, and at 9.30 P.M. (about two hours after she was bled, during which time no anesthetic was given her) a living child was born.

These are two of a number of similar cases that I could report, and are selected only because the data are accessible.

Meigs, in his *Practice of Midwifery* (2d ed., 1842, p. 182), after due caution as to the amount of blood generally necessary to be taken, its effect on the pulse, etc., says: "But, on the other hand, where symptoms strongly threatening of apoplexy, convulsions, pulmonary hemorrhage, inflammation, etc., make their appearance, the lancet should be used in the most fearless manner. The same is true of those cases where a great relaxation of the tone of the tissues is required for some special and pressing object, such as the relaxation of a strictured vagina or a very rigid uterus, the removal of a violent congestive or inflammatory accumulation of blood in the brain, etc."

Rigby, in his *System of Midwifery* (American ed., 1841), recommends venesection as one of the remedies in rigidity of the os uteri, contracted vagina, stricture of the uterus, and in lying-in women with pleurisy or pneumonia.

Cazeaux, in his *Treatise on Midwifery* (American ed., 1868), in speaking of the treatment of "rigidity of the cervix" (p. 699), says: "Prolonged baths, employed from the beginning of the labor, and bleeding from the arm, if not contra-indicated by the general condition of the patient, are the only means which may be used under the circumstances." But in the next paragraph he says: "Still, if the labor should be extremely prolonged, and by its duration seems likely to endanger the life of the mother, it would be right to make a few incisions upon the lateral parts of the cervix." The same eminent author, under the head of "Spasmodic Contraction of the Neck" (of the uterus), after mentioning (p. 700) "forcible introduction of the hand and multiple incisions upon the neck," says (p. 701): "Bleeding, general bathing, and laudanum injections may be employed usefully under these circumstances also, though it sometimes happens that the contraction

of the internal orifice persists notwithstanding. Under these circumstances, should version be judged necessary, the most serious difficulty may be anticipated in passing the hand through the retracted part; and if the application of the forceps be deemed requisite, as it would if the head were already engaged, but delayed by the retraction of the internal orifice, this latter circumstance, by arresting the shoulders, would render the delivery impossible. It is then we must have recourse to the measures so much vaunted and so often employed by Dewees with success, namely, to bleeding in the arm pushed *ad deliquium animi*. But, in order to avoid drawing too great a quantity of blood, the patient should be directed to stand up, if possible, and as soon as fainting occurs, she is to be replaced on the bed, when, according to the American accoucheur, the relaxation in the retracted orifice, produced by the syncope, will be such that the pelvic version or the extraction of the head by the forceps can always be performed." Furthermore, Cazeaux (p. 701, *op. cit.*) says that "in a natural labor by the pelvis the retraction of one of these orifices may likewise arrest the head. Under such circumstances, if the source of difficulty is confined to the external one, numerous incisions might be made in the ring of the os uteri; but if it is at the internal orifice, Dewees's plan should certainly be followed." When the woman's general condition does not admit of bloodletting, Cazeaux recommends "opiates in full doses and inhalations of chloroform." Professor Meigs (p. 181, *op. cit.*) says: "Professor Dewees has been justly celebrated for the boldness and good judgment with which he resorted to bloodletting in some cases of labor."

Half a century has elapsed since the majority of the authorities quoted taught that venesection is beneficial in certain conditions of labor, but few teachers of the present day recommend it in obstetric practice. Dr. Davis, in his *Manual of Practical Obstetrics*, does not mention venesection in rigidity of the os and cervix, but speaks of bloodletting in puerperal eclampsia. On page 172, he says: "In apoplectiform cases, where plethora is excessive, bleeding may be practised with marked temporary benefit. No permanent benefit can be expected, as this expedient will not exercise more than a temporary influence over the patient." This is contrary to an experience in which, after bleeding *freely*, the convulsions cease, the os dilates rapidly, and the child is born in a surprisingly short time. Full and free bleeding is the *sine qua non* in puerperal eclampsia.

Such is the attitude of our obstetric teachers in regard to venesection that the general practitioner stands aghast at the mention of bloodletting under any circumstances, and, drifting with the current of fashion and public opinion, in our eagerness to discover some new or novel remedy or means to accomplish our object, we ignore the old and proved remedies.

If, as its advocates claim, venesection causes relaxation of the rigid os uteri and other parts of the genital organs sufficiently to admit of a speedy termination of labor, the inference follows that it may, to some extent, serve as a preventive of laceration of the womb and other parts of the genital tract, and, instead of making incisions into the womb in order to facilitate labor, thereby furnishing a wound for the gynecologist to close, or leaving it an open sore to act as a source of septic infection, carcinoma, etc., we may, by the simple and harmless process of extracting a few ounces of blood, prevent such dreadful results (first described by Emmet) as follow laceration of the womb and other parts. These remarks are scarcely applicable to those cases in which there is cicatricial tissue from old lacerations or from multiple incisions of the os in labor. Does it not seem inconsistent for the gynecologist to teach that a lacerated wound of the os uteri is the source of so much suffering and of untimely death to women, and the obstetrician to teach that it is our duty to produce numerous incised wounds of the same parts, and that we may do so with impunity? We would detract nothing from the wonderful discoveries by which all departments of medical science have advanced; but has the old process of childbirth advanced with these discoveries, so that what was advantageous in labor fifty years ago is useless or injurious now?

Venesection is one of the most rational and effective means at our command, not only in the class of cases under consideration, but in some inflammatory conditions—for instance, in acute pleurisy, which venesection will more speedily and permanently relieve than any other known remedy. The same is true of some cases of acute croupous pneumonia. How bleeding affects the diplococcus of pneumonia, we leave the pathologist to determine.

Respectfully,

J. E. COPELAND, M.D.

ROUND HILL, VA.

THE RELATIVE LOCALIZATION OF CARCINOMA IN FEMALES.

To the Editor of THE MEDICAL NEWS,

SIR: In an editorial in THE MEDICAL NEWS of January 7, 1893, p. 21, the following statement is made: "The statistics of carcinomata among women show that in about 70 per cent. of the cases the disease is located in the organs of generation, most frequently in the breast. In the majority of these cases, again, the patients are either unmarried or, if married, have never borne children, or so few as to fail to satisfy the normal tendency to activity in the organs concerned."

In Pozzi's *Gynecology* it is said: "Women are more subject to cancer than men, and it is the uterus which is most frequently attacked. This fact has been proved beyond doubt by J. Y. Simpson's statistics in the *Annual Report of the Registrar-General for England* of the years 1847–61. During the period which may be called uterine life of the woman their frequency is most manifest, that is, from puberty to the menopause, when it attains its maximum. After the uterus, the breast is most often attacked."

In the fifth edition of Thomas's *Diseases of Women* is the following: "Cancer is an affection of frequent occurrence, and is more frequently seen in the uterus than any other organ. According to Rokitansky the following average scale may be adopted as representing the preference of cancer for various organs: First, the uterus, the female breast, etc. Statistics prove that cancer is nearly three times more frequent in women than in men, and more than three times more frequently met with in the uterus than in any other organ of the female."

Pozzi says: "Local predisposing causes which have

been mentioned are laceration and metritis of the cervix. Mangin has made histological researches of great interest on the point. He also instances the effect of repeated parturition, but it is possible that this repetition acts only by the laceration and inflammation which are its consequences." Thomas says: "Cancer of the uterus is more frequently observed among multiparæ than nulliparæ. Of Scanzoni's 108 cases—

8	had been delivered	. . .	11 times
3	"	" . . .	10 "
14	"	" . . .	8 "
13	"	" . . .	7 "
21	"	" . . .	6 "
10	"	" . . .	5 "
3	"	" . . .	4 "

"The results of Mr. Sibley's investigation in the Middlesex Hospital go to prove this fact. He found the average number of children borne by women suffering from this disease was 30 per cent. in advance of the average of all marriages. With reference to uterine cancer, my experience certainly goes to sustain the opinion of Breisky, Emmet, and others, that epithelioma of the cervix very generally engrafts itself upon a laceration."

Which statements are correct—those of the editorial or those quoted from Pozzi and Thomas?

Respectfully yours, Adelaide Lambert.

263 Orange Street, New Haven, Conn.

[Opinions are divided upon the subject. Thus, in the last edition of Thomas's work, edited by Mundé (1891), p. 805, it is stated that "This disease (cancer of the breast) is exceedingly common, being, we believe, even more common in the female sex than cancer in that other favorite locality, the cervix uteri." We only stated our own belief.—Ed. News.]

ABORTIVE FREE CRUCIAL INCISIONS IN THE TREATMENT OF CARBUNCLE.

To the Editor of The Medical News,

Sir: The Medical News of February 11, 1893, p. 159, contains an article on "The Treatment of Carbuncle." I believe that, as a result of personal experience, I can improve upon the treatment given.

I have for some time been in the habit of making free crucial incisions, deep enough to expose all surfaces and tissues involved. After hemorrhage has been arrested I apply the following ointment:

℞.—Acid. salicylic.	2 parts.
Lanolin. (previously heated, but not melted)	2 parts.
Cosmolin.	1 part.

Misce sec. art. Apply morning and evening upon lint held in place by sufficient adhesive plaster to cover the entire indurated surface.

In this way I produce an open wound, and soon a line of demarcation will separate the dead from the living tissue. The "core" thus artificially formed becomes a foreign and inert substance, which can easily be dissolved and separated from the living tissues by a spray of a 50 per cent. solution of hydrogen dioxid. After this has been accomplished I treat the wound with antiseptic dressings.

By this method of treatment I produce abortion (without the time-honored poultices) and with great amelioration of suffering and pain.

I have used this mode of treatment in a large number of cases, and have experienced a speedy and early recovery. I find the salicylates to be good germicides.

Yours truly, A. C. Wentz.

Hanover, Pa.

NEWS ITEMS.

Association of American Physicians.—The preliminary program of the eighth annual meeting, to be held in the Army Medical Museum and Library Building, Washington, D. C., May 30, 31, and June 1, 1893:

The President's Address, by Dr. A. L. Loomis, of New York.

Discussion on Myxedema. Referee, Dr. F. B. Kinnicutt, of New York; co-referees, Dr. J. J. Putnam, of Boston, and Dr. M. Allen Starr, of New York.

"Sporadic Cretinism in the United States," and "Supplementary Report on Amebic Dysentery," by Dr. Wm. Osler, of Baltimore.

"Some Problems in the Etiology and Pathology of Texas Cattle Fever and their Bearing on the Comparative Study of Protozoan Diseases," by Dr. Theobald Smith, of Washington.

"Experiments with the Bacillus Diphtheriæ," by Dr. A. C. Abbott, of Philadelphia.

"The Parasitic Nature of Cancer," by Dr. Heneage Gibbes, of Ann Arbor.

"A New Pathogenic Bacillus," by Dr. H. C. Ernst, of Jamaica Plains.

"Gonorrheal Myocarditis," by Dr. W. T. Councilman, of Boston.

"The Prophylaxis of Cholera, with especial reference to Immunization," by Dr. E. O. Shakespeare, of Philadelphia.

"Creasote in the Treatment of Tuberculosis," by Dr. J. T. Whittaker, of Cincinnati.

"On a Simple Continued Fever," by Dr. G. Baumgarten, of St. Louis.

"The Treatment of Typhoid Fever," by Dr. S. A. Fisk, of Denver.

"The Intestinal Treatment of Chlorosis," by Dr. F. Forchheimer, of Cincinnati.

"Probable Origin and Early Symptoms of Certain Chronic Diseases of the Kidneys," by Dr. C. S. Bond, Richmond, Ind.

"The Reactions of the Urine with Ether," by Dr. A. H. Smith, of New York.

"A Study of Addison's Disease and of the Adrenals," by Dr. W. G. Thompson, of New York.

"Two Cases of Cystic Calculus," and "Two Cases of Diaphragmatic Hernia," by Dr. James Tyson, of Philadelphia.

"Subphrenic Abscess with especial reference to Cases which Simulate Pneumothorax," by Dr. A. L. Mason, of Boston.

"Subphrenic Abscess," by Dr. S. J. Meltzer, of New York.

"Sarcoma of the Lung, with Specimen," by Dr. D. W. Prentiss, of Washington.

"Pulsating Pleural Effusions," by Dr. Jas. C. Wilson, of Philadelphia.

"The Importance of Uterine Displacements in the Production of Vomiting during the Early Stages of Pregnancy," by Dr. G. M. Garland, of Boston. To be discussed by Drs. W. T. Lusk and W. M. Polk.

"Experimental Observations Concerning the Nature of Chorea," by Dr. H. C. Wood, of Philadelphia.

Paper (title to be announced later) by Dr. W. M. Polk, of New York.

The Fourth Section of the International Congress of Charities, Correction, and Philanthropy, to be held in Chicago in 1893, is to consider all matters relating to the commitment, detention, care and treatment of the insane. The Committee of Organization of the Congress has appointed Dr. G. Alder Blumer, Superintendent of the Utica State Hospital, Utica, N. Y., as Chairman of this Section, and Dr. A. B. Richardson, Superintendent of the Columbus Asylum for the Insane, Columbus, Ohio, as its Secretary, and has authorized and requested them to complete its organization, to extend invitations, and to prepare a program for its work.

The Section will hold five meetings of about two hours each, commencing June 12th, 1893, and will also have charge of one of the general sessions of the Congress, viz., that held on the morning of June 17th.

It is desired that this shall be a truly international gathering for conference on the subjects allotted to this Section, and all who are interested in the commitment, detention, care, and treatment of the insane, are cordially invited to be present, to contribute papers, and to take part in the discussions.

The papers and proceedings will probably be printed as a separate volume, and it is hoped that this will represent the best methods and the best work in each of these departments in all parts of the world.

In the selection of topics, those of international interest and utility should have precedence over those of a more local character; for instance, histories of the movements in which alienists the world over are interested, presentations of the actual status of work in behalf of the insane, in any of its numerous departments, and discussion of living questions, might fitly occupy the time and attention of the Section.

Persons desiring to present papers, or to share in the discussions, are requested to communicate with the Secretary at once. The period of time allotted for the preparation of the program is necessarily brief, and it is essential that all who are willing to assist in this work should act promptly.

Sickness and Mortality Statistics of the U. S. Navy.—The sick of the Navy during the year 1891 were 12,151, a decrease of 698 as compared with the previous year, when the number was 12,849.

The sick were distributed as follows: 7934 on vessels afloat and receiving-ships, 1733 in hospitals, and 2484 at navy yards and stations.

The daily average number of sick on vessels afloat and receiving-ships was 162.29, which was practically the same as the previous year, when it was 161.86. The average number of days each case was under treatment was 7.46, while the previous year the average was 6.86 days.

The total number of sick days of the force afloat and on receiving-ships represented a loss to the Government of 59,237 days, or an average of 162.29 men on the sick list daily. Of the 7934 patients on the sick list, 6968 were returned to duty, 727 were invalided to hospitals, 46 were discharged from the service, 41 died, and 152 continued under treatment at the close of the year.

The number of deaths during the year 1891 was 91, distributed as follows: 34 in the hospitals, 16 at the yards and stations, and 41 on vessels afloat and on receiving-ships, making a ratio of 7.91 in a thousand. These figures, as compared with previous years, show a very gratifying result, being the lowest death-rate in the Navy for many years, and which can be attributed to the absence throughout the year of casualties and epidemic diseases.

The death-rate for the year 1888 was 12; for 1889, 18; for 1890, 9; and for 1891, 7.

The Section on Therapeutics of the Pan-American Medical Congress.—It is the earnest desire of the officers of the Section on Therapeutics of the Pan-American Medical Congress that both specialists and general practitioners should contribute articles to its proceedings. Those desiring to read papers at this meeting should at once notify Dr. H. A. Hare, President of the Section, Philadelphia, of their intention, and should send him by July 10th abstracts of papers, in order that these may be translated into the three official languages of the Congress and published in the program.

The American Association for the Study and Cure of Inebriety will hold a special meeting at the hall of the New York Academy of Medicine, No. 19 West 43d Street, New York City, March 23, 1893, at 8 P.M. The subject for discussion will be "Specific Remedies for the Treatment and Cure of Alcoholic and Opium Inebriety." Short papers will be read by Dr. Norman Kerr, of London; Drs. Kiernan, Clevenger, and Moyer, of Chicago; Dr. Hughes, of St. Louis; Dr. Peterson and Clark Bell, Esq., of New York; Drs. Mason, Mattison, Mann, and Wood, of Brooklyn; Dr. Day, of Boston; Dr. Crothers, of Hartford; Dr. Russell, of Winchendon, Mass.; Dr. Quimby, of Jersey City; and others.

Suicides of the Insane in New York.—A typographical error occurred in THE NEWS of March 11th, p. 260. The number of suicides of patients in the asylums of the State of New York was given as 15 per cent. It should have been 15 per annum.

BOOKS AND PAMPHLETS RECEIVED.

DIPHTHERIA—A CLINICAL STUDY.[1]

BY WILLIAM P. MUNN, M.D.,
OF DENVER, COL.,
ASSISTANT PROFESSOR OF GENITO-URINARY DISEASES AND CLINICAL SURGERY IN THE UNIVERSITY OF DENVER; GENITO-URINARY SURGEON TO THE ARAPAHOE COUNTY HOSPITAL; PHYSICIAN IN CHARGE OF QUARANTINE, AND ASSISTANT HEALTH-COMMISSIONER OF THE CITY OF DENVER.

EMPHASIZING the importance of diphtheria and its perfect understanding by physicians, it is only necessary to consider for a moment its constant prevalence and its fatality, as shown by the mortality reports of all cities. In Denver, for example, it has, during the past five years, caused from five to ten per cent. of the total number of deaths. The following table gives the exact figures:

Year.	Total deaths.	Diphtheria deaths.	Croup deaths.	Per cent. of deaths due to diphtheria.	Per cent. of deaths due to diph. and croup
1888	1729	77	43	4.5	7
1889	1808	77	28	4.3	5.8
1890	2530	210	50	8.3	10.6
1891	2118	145	30	6.8	8.25
1892[2]	1578	75	9	4.75	5.3

A rough estimate of the percentage of fatal cases may be made from a consideration of the number of reported cases of sickness and the number of deaths. There were 440 cases of diphtheria reported during 1891, with 145 deaths, a mortality of 33 per cent.; adding croup there were 470 cases, with 175 deaths, a mortality of 38 per cent. During the first eleven months of 1892 there occurred 281 cases of diphtheria, with 75 deaths, a mortality of 26 per cent.; or, adding croup, there were 290 cases, with 84 deaths, a mortality of 29 per cent. The limits of this paper prevent any proper consideration of sanitary precautions for the prevention of diphtheria, which will be reserved for a future time.

The recent literature of diphtheria all tends toward a more certain understanding of its nature and more definite objects to be attained by treatment.

Jonathan Hutchinson voices the opinion of ultra-conservatism when, admitting the weight of the facts in reference to germs causing this disease, he says that he "is not yet convinced that they cause it." Bacteriologic investigators, on the other hand, are ready to prematurely credit the clinical phenomena to one germ only, and to call only those cases in which it is present "true diphtheria"—classifying all other cases, though clinically similar and equally fatal, as "pseudo-diphtheria," or as some other variety of anginose condition.

It is not unreasonable to assert that similar pathologic and clinical phenomena may be caused by a number of different organisms, existing separately or in company. No one of these germs is to be regarded as the sole and specific organism; one may be less malevolent than the other; but the disease which it causes is clinically indistinguishable from that due to the other germ—it is equally contagious; the malevolent condition may at any time be added to the benevolent form; therefore, the disease is diphtheria, and is to be so classed for treatment and for hygienic precautions.

A fairly accurate definition is this: The disease-process or combination of processes known to us as diphtheria is both infectious and contagious. Its cause is an albuminous material of intensely poisonous character resulting from the growth, usually within the body or upon one of its surfaces, of any of the following microörganisms: 1, the bacillus diphtheriæ of Klebs and Loeffler; 2, the streptococcus diphtheriæ of Prudden; 3, a simple micrococcus resembling that described by Roux and Yersin.

These germs and the products of their activity give rise to a series of clinical phenomena so similar as to be practically indistinguishable. The ordinary genesis of the disease is probably as follows: 1. The germ obtains lodgment upon some mucous surface of the body, most usually in the upper respiratory passages, as a rule upon the posterior pharyngeal wall, in the palatine folds, on the tonsils, or in the nose (these localities are named in the order of frequency of primary involvement), and less frequently in the larynx. 2. The germ finding suitable pabulum grows and multiplies theron, and, as a result of its growth, the toxic albuminous body characteristic of the disease is formed and set free. 3. A series of local pathologic changes then occur, as follows: The epithelial covering of the mucous membrane is devitalized and cast off, and almost coincidentally a fibrinous exudate occurs, which, according to the

[1] A paper read before the Denver and Arapahoe Medical Society, December 13, 1892.

[2] First eleven months.

rapidity of its formation, may or may not hold the dead epithelium in its meshes, and according to the concentration and virulence of the toxic albumin or "toxin," may or may not invade the basement membrane and deeper tissues underlying the mucous surface. 4. From this distinctly local disease-focus there now occurs absorption of all of the products of the pathologic processes there occurring; the toxic products of the diphtheria-germ (bacillus, streptococcus, or micrococcus, as the case may be) are accompanied into the blood and into the lymphatics by the toxins of those other swarming microörganisms which, as a rule, coexist, and which multiply readily in the necrotic tissues; sometimes the germs themselves find their way into the circulation, infecting both the blood and distant organs and structures.

As a result of this systemic invasion there occurs, usually, although not with absolute regularity, general malaise, anorexia, perhaps nausea and vomiting, rise of temperature, increased pulse-rate, lowered blood-pressure, and weakened heart-action; the excretory organs may be affected in a manner ranging from absolute stimulation to complete paralysis; the bowels are usually inactive. These clinical features are far from constant, and some of them are of little significance as compared with their relative importance in other diseases. Thus, in my experience, the rise of temperature means almost nothing in diphtheria, while the circulatory changes are of supreme importance. Certain of the clinical changes are of greater or less intensity and of greater or less importance, according to the saturation of the system with pathologic products other than the specific toxins of diphtheria. It is certain that these other products, originating in a necrotic process are identical with those of ordinary septicemia; the clinical phenomena are exactly similar to those of ordinary septicemia, and emphasize the point which is of so great importance in reference to a proper understanding of the nature of diphtheria and its proper treatment, viz., that it is a septic disease. Or, perhaps a more accurate expression of the fact is that diphtheria pure and simple, a result of intoxication of the system with diphtheria-germs or their toxic albumins, is almost invariably accompanied by septicemia due to the absorption of other septic and necrotic products.

As already stated, the febrile conditions are not constant; neither are they found to exist coincidentally to such an extent as in other diseases; *e. g.*, the temperature may remain constantly normal or subnormal, while the pulse will range from 120 to 160 per minute. Then the rapid pulse of diphtheria is almost never full and bounding, but is almost always weak and compressible, often thready. Even when febrile conditions are marked there is a strange absence of delirium; in fact it is often noted that patients, especially children, suffering from fatal forms of diphtheria are rational up to the moment of death, thinking, speaking, and planning in the most connected and sensible manner, and, as a rule, recognizing the approach of the great change and absolutely welcoming it. When the septic conditions are most intense, coma occurs. It has been determined that coma is probably due to an albuminous body existing in the germ and not formed as a result of its growth. This body is acid in reaction, of the nature of a protein, and differs radically from the toxins. The manner in which this body is set free—if it is set free—and the way in which it acts—if it does act—to produce the characteristic coma of diphtheria, are not as yet known. I am inclined to think that the further study of this problem and of the reciprocal actions and physiologic influences of these organic bodies may yet yield information of value in regard to the development of the antitoxin of diphtheria.

Returning, however, to the local lesion, which is worthy of extended observation and investigation, usually described and often existing as a yellow or grayish-yellow membrane, I have observed it more frequently in the beginning as a pearly-gray pellicle of extreme tenuity, often simulating the condition due to edema of the mucous and sub-mucous tissues. At other times a tiny patch resembles muco-pus filling a crypt in one of the tonsils, or hidden in the palatine recess, from which as a center it spreads quickly. Again, a slender, filmy, gray line appears first, crossing the tonsil at an irregular angle or hidden in one of the faucial folds. A favorite location is the posterior surface of the naso-pharynx, where the germ is really most likely to lodge, impinging there at the point from which the incoming air-current is deflected downward. The beginning membrane is not readily discovered at this point, being hidden from view by the soft palate. Vocalization and the coincident rise of the palatal curtain will often reveal a hitherto hidden patch of membrane.

The rapidity of the extension of the membrane is quite variable. In some few cases the first-observed patch, film, or line, will remain stationary and of doubtful character for as long a period as thirty-six hours; more usually it spreads, so that in twenty-four hours an area of one or two square inches is covered; while more rarely it increases with alarming rapidity in the course of a few hours, so that a spot which in the early afternoon seemed insignificant or of doubtful character has by early evening become a dense necrotic mass, filling the whole of the fauces, obstructing the posterior nares, preventing deglutition and interfering with respiration. The little patient sits up in bed with the mouth open, partly for facility in respiration, partly because the

swelling of the tonsils and cervical glands has become so great and so painful as to prevent the closing of the jaws. Thus in a few hours the local condition may become so serious as to endanger life, even although the systemic invasion has not yet been great. Cases of this class are, as a rule, rapidly fatal. The membrane thus early obtaining vantage-ground, extends rapidly both upward and downward, the nose becomes filled with a dense fibrinous mass, totally occluding its caliber and of such consistency that it can with difficulty be bored through with an ordinary probe; laryngeal stenosis occurs early, and the patient dies in less than seventy-two hours, regardless of the means adopted for relief. Intubation and tracheotomy seem to be equally valueless in these overwhelming cases, for after the first twelve hours the absorption of toxins and of septic material from the great necrotic mass covering and filling pharynx, nose, and larynx, is so great and so rapid that the blood is practically disorganized, the nervous system overwhelmed, the heart enfeebled beyond aid, and death is almost inevitable.

Rapid membrane-extension, such as is here described, is probably dependent upon three causes; (*a*) intensity or virulence of the poison, which may be due to high vitality or activity of the germ or to an especially favorable medium existing for its growth, the secretions of the individual being at the time in condition to furnish a good cultivation-fluid; (*b*) erosion of the epithelial covering of the mucous membrane; this condition may pre-exist or may be furnished at the time by ill-advised local medication with remedies which devitalize the epithelial cells and thus denude the mucous membrane; (*c*) idiosyncrasy of the patient. In some families, diphtheria occurs at periods remote from each other, the hygienic conditions differing at each time, but the type of the disease in the family is almost invariably the same, and the patients almost invariably die. The members of some families possibly have a lowered resisting power, both of the local cells to the germ, and of the system to the poison. The recurrence of the malignant type of the disease in some families can only be explained by some such supposition. I have observed that the members of such families, while otherwise perfectly healthy, seem to have a tendency to catarrhal inflammations of the mucous membranes of the digestive and genito-urinary tracts as well as of the respiratory passages.

The usual factors of fatality-causation in diphtheria may be stated as follows:

1. Extensive involvement of mucous surfaces.

2. Rapid absorption of disease-products and consequent constitutional poisoning.

3. Laryngeal stenosis.

4. Pre-existing conditions that lessen the resisting power of the system.

Practically, the second and third factors are dependent upon the first, viz.: Extensive involvement of mucous surfaces; and the preponderating influence of this factor in causing death is very forcibly shown in the following analysis of cases in which I have preserved a record of the extent of membrane-formation.

CASES NOTED—128.

Location of membrane.	No. of cases.	No. of deaths.	Per ct. dying.	Per ct. of all.
Fauces only	44	1	2	34
" and palate	29	1	3.5	23

Bowels involved	1	1	100	—
Cases not treated	11	7	64	—
" treated	117	18	15 33	—

The causes of death were as follows: Septic intoxication, 8; laryngeal stenosis, 7; cardiac paralysis, 6; hemorrhage from the bowels, 1; suppurative nephritis, 1; unknown, 2; total, 25.

In the one hundred and twenty-eight cases, operative interference on account of laryngeal stenosis seemed to be demanded, and was proposed, in nine cases. Five declined operation, and all died, three of the stenosis and two of septicemia. One accepted, but operation was deferred, and ultimate recovery ensued without it. Three were operated upon, two by tracheotomy and one by intubation, and all died. Each of these patients was practically moribund before operation was permitted.

It will be noted that only three laryngeal cases recovered, and that of the fatal cases, all but four had nasal and all but nine had laryngeal involvement. That this fatality is largely due to the extent of membrane from which absorption can take place is evidenced by the fact that only seven deaths occurred from a local cause (laryngeal stenosis), while sixteen deaths were due directly or indirectly to septic conditions.

In only five cases, or four per cent. of the number of which notes were preserved, were the fauces free from membrane; in two of the five, no membrane

was visible at any time; in two it appeared only on the hard palate; and in one it was visible only under the tongue.

Of eighty-one cases in which membrane was limited to the fauces, the palate, and the tongue, but two died; while of forty-seven cases in which the nose and larynx were involved, twenty-three, or forty-nine per cent. died. Of nineteen having laryngeal membrane, seven died of stenosis; deducting these, we find that nine of twelve died of septic intoxication and cardiac paralysis, conditions due directly to the absorption of material from the local disease-focus. Of the nasal cases, twenty-one of forty-five (or forty-seven per cent.) died, a somewhat lower rate on account of the greater accessibility of the nasal cavity to treatment, but still a large number of deaths.

The four cases in which the membrane is recorded as appearing on the tongue are of special interest. The first was in a child two years old; the disease was ushered in by a severe convulsion, during which he bit the tongue almost in two. The membrane developed on the wounded surface and on the dorsum of the tongue. The other three cases were all in adults and all in one family; the membrane was a well-defined persistent patch under the tongue. Each of the patients had previously nursed a patient ill with the disease, and, although warned of the danger, persisted in reading books and magazines that had been in the sick-room from the beginning of the illness in the house. They had the habit of moistening the thumb under the tongue, preparatory to turning the leaves of the book. All four patients recovered.

The four cases in which the eyes were involved were of especial interest, as the process seemed in each case to spread through the lachrymal duct. Three of them died when the palpebral conjunctiva had been invaded; the fourth one recovered, affording me the undesirable opportunity of observing the progress of the destructive processes in both eyes. The left eye was first involved, membrane-formation having evidently taken place already in the duct, which was occluded from distention of the sac. The lower lid and then the upper one was invaded, followed by the ocular conjunctiva, which was rapidly covered, the membrane advancing with rapidity from periphery to center, suddenly choking off the nutritive supply of the cornea and causing it to slough forty-eight hours after the first invasion of the eye.

The sequence of events as observed on the conjunctiva of the lids was as follows: An intense hyperemia, then, twelve hours later, a roughened, granular appearance, with apparent epithelial desquamation; this being quickly followed by marked anemia (perhaps only the deceptive appearance of the forming translucent veil of membrane). Twelve hours later there was a well-formed membrane, about one-sixteenth of an inch in thickness, lining the entire surface of both eyelids, and beginning to push on to the ocular conjunctiva.

In the right eye the changes were a little slower, but in practically the same order. Increased intra-ocular tension was noted by Dr. Chase, who had kindly attended the case with me, and immediate preparations were made for paracentesis; but, before we could return, rupture had occurred, and the cornea also ultimately sloughed in part.

When recovery from the general disease occurred it was noted that a small portion of the lower segment of the cornea remained, and there was a dim perception of light. Dr. Chase kindly kept the eye under treatment, and proposed making an effort to form a new pupil, but the family removed to St. Louis, and all trace of the patient was lost.

This, and one of the fatal cases involving the eyes, had scarlatina immediately antecedent to their diphtheria, and the nose was seriously involved in all four cases.

The two fatal cases, in which membrane appeared in the ears, were also accompanied by nasal involvement, and the membrane extended through the Eustachian tubes, perforated the drum-membrane, and pushed out through the external meatus. Several other cases—all fatal—had middle-ear suppuration and perforation as a result, but a well-defined membrane was only detected in the two cases recorded.

The case of diphtheric enteritis recorded was under my personal observation, but not attended to by me. The patient was eleven years old, and the membrane was present in the fauces and in the nose. Intestinal hemorrhage was first noted on the fifth day of the disease, increasing in amount and frequency until death occurred on the morning of the seventh day. The blood was dark-colored and had the same foul odor noticed on the breath in those cases in which the faucial membrane is thick and gangrenous.

One death, credited to laryngeal stenosis, occurred under the following circumstances: There was no membrane in the larynx, but an extensive and tough one in the fauces. About the sixth day this began to separate; a large piece loosened spontaneously, flapped down, was drawn into the larynx during inspiration, and the boy choked to death.

In two instances I have observed erysipelas coincident with diphtheria, and one of these patients, a young man, seventeen years old (Case LX), recovering perfectly from both his erysipelas and diphtheria, was immediately attacked by characteristic typhoid fever with all the classical signs and symptoms: rose-spots, typhoid tongue, sordes,

typhoid temperature, tympanites, and ileo-colic pain, dying of intestinal hemorrhage in the third week of the typhoid fever.

Diphtheria is a disease of childhood rather than of adult life, as the following analysis of cases, according to age, will show:

1 year and under,	8 patients.	5 died.	62.5 per cent.
Over 1 year, not over 2,	12 "	3 "	25 "
" 2 years, " 3,	9 "	3 "	33.3 "
" 3 " " 4,	10 "	2 "	20 "
" 4 " " 5,	11 "	5 "	46 "
" 5 " " 10,	32 "	5 "	16 "
" 10 " " 15,	12 "	1 "	8 "
" 15 " " 20,	10 "		
" 20 " " 30,	16 "		
" 30 " " 40,	5 "		
45 years of age,	1 patient.	Recovered.	
47 " "	1 "	Died.	
52 " "	1 "	Recovered.	
	128	25	

Fifty of 128, or 40 per cent., were under five years of age, and 18 of the 50, or 36 per cent., died.

Eighty-two of 128, or 65 per cent., were under ten years of age, and 23 of them, or 28 per cent., died.

Ninety-four of 128, or 75 per cent., were under fifteen years old, and 24 of them, or 26 per cent., died.

There were 34 patients above fifteen years of age, and of them but one died. This was a man, forty-seven years of age, of dissipated habits, the disease well advanced before he came under treatment, and he died suddenly of cardiac paralysis when apparently convalescent.

The causes of increased prevalence and increased mortality among children are various. A sore-throat is usually not recognized and treated so early in a child as in an adult; treatment, when begun, is more difficult to carry out efficiently and thoroughly; the resisting power of the child's organism is less than that of the adult. The preponderance of fatality among very young children (under one year) is very marked, especially when we consider their comparative immunity from the disease. It will be noted that there were but eight cases of one year old and under. The youngest patient in the series was eight months old. It is a comparatively rare occurrence for nursing babes to contract diphtheria, even when exposed to it. But of those who do take it an extremely large percentage die; five of eight such cases, or 62.5 per cent., under my own care, died. Most of these very young patients live but a short time after their illness is recognized.

THE RELATIONSHIP OF SCARLET FEVER AND DIPHTHERIA.

The streptococcus diphtheriæ of Prudden cannot be distinguished by its physical characters from the streptococcus that causes scarlet fever, or from the one that causes erysipelas. It is not impossible that the same germ may have a different life-history under different circumstances; that environment may cause it, after many generations, to be endowed with new properties, malevolent or benevolent, as the case may be.

It seems probable that the streptococcus of diphtheria more commonly occurs in connection with scarlatina, and one observer (Heubner) is quoted as maintaining that what he calls "scarlet-fever diphtheria" is not so severe as ordinary diphtheria, that the tissue-necrosis is not so marked, and that laryngeal stenosis and paralysis very rarely result from it.

In the cases upon which this study is based there were 23 that occurred coincidently with or immediately following scarlatina, and 6 (25 per cent.) of these cases died, all but one evidently dying of the diphtheria. The nose was involved 9 times in the 23 cases and the larynx 4 times. In addition, 15 persons who had been exposed to scarlatina or to scarlatina diphtheria contracted diphtheria evidently of the common form, without any scarlatinal complication, and of the 15 one died. The nose was involved 3 times, and the larynx not at all in these 15 cases.

I have been told that in Bremen and Stockholm there occurs an overwhelmingly large number of the variety of cases which require intubation or tracheotomy in order to avoid a fatal termination of the case within a few hours of the onset of the disease. The percentage of such cases occurring here is small. The literature of the subject seems to show that in New York and Boston operative interference on account of laryngeal stenosis is called for oftener and earlier than it is in Denver. It seems possible that these cases are of the variety due to the more malevolent germ, said to be the Klebs-Loeffler bacillus, while a great portion, though of course not all, of the cases of slower onset and milder manifestations, are due to the less malevolent germ, probably the streptococcus.

The grayish or yellowish-white pellicle that so often covers the tonsils from about the third to the seventh day of scarlet fever may not always be a diphtheric membrane; yet I am inclined to think that it usually is, and when the pellicle spreads on to the hard palate and clings there persistently for many days, recurring as quickly as it is removed; when it thickens into a grayish mass, pultaceous on the surface and harder beneath, and accompanied by its peculiar sickening odor of decomposition; when, preceded by an acrid discharge which erodes both mucous membrane and skin, it enters the nose and there thickens until it occludes the whole cavity, perhaps pushing—ashy or even black in color—out of the nostrils on to the lip; when it creeps through the lachrymal duct out of the

puncta, lines the conjunctival sac, and chokes off the nutrient vessels of the cornea; when it passes along the Eustachian tube, breaks through the tympanic membrane and makes its appearance in the external ear; when it passes down into the larynx, covers the cords, and, occluding the glottis or slipping down in thinner form, invades the bronchi to their minutest subdivisions; then, whether it has preceded, or succeeded, or accompanied scarlatina, I recognize it as diphtheria, capable of spreading the contagion of diphtheria, with or without any accompanying disease, and of communicating diphtheria to persons who have previously suffered from and thus been made immune to the accompanying scarlatina.

There is a variety of deposit on the tonsils during scarlatina which, developing in the throat at the height of the anginose inflammation, disappears in a few days, never having at any time attained any great thickness, not spreading to any great extent, and usually capable of being easily removed with a swab. This I have not classed as diphtheria. But membrane of the more truly diphtheric type often occurs at this time, or its occurrence may antedate the appearance of the rash by several days, or even a week; or again, membrane may suddenly make its appearance during the eruption, or after the efflorescence has subsided and desquamation has far advanced.

It is peculiar that this truly diphtheric process occurs often in persons who have only been exposed to ordinary scarlatina, there being no diphtheria existing at the time in the neighborhood, the patients affected having previously suffered from scarlatina. Examples of this fact are Cases VII, XXVI and XVII of the series reported in this paper. They were exposed to scarlatina simplex, but took diphtheria; one developed a rash four days after having membrane in his throat. Cases IV and V, who had previously suffered from scarlet fever, contracted simple diphtheria of a malignant type from such an exposure. Case LXXV, a mother who had suffered from scarlet fever in childhood, nursed her children (Cases LXXIII and LXXIV), suffering from scarlet fever complicated with diphtheria, and contracted diphtheria alone. Both children died of cardiac paralysis. The mother had membrane in the nose and on the palate to within an inch of the teeth, had palatal paralysis as a sequence, and was a long time in regaining her strength.

It would have been interesting to have had a bacteriologic examination in these three cases to determine whether the infection was from the streptococcus, or the bacillus, or from both at once.

Case CV was a woman who had scarlet fever in childhood, nursed her two children through scarlatina simplex, and was immediately taken down with a severe type of diphtheria.

Cases CVI and CVII were a mother and child in a family four other members of which had just recovered from simple uncomplicated scarlatina. The fifth child, exposed only to the scarlatina, contracted both this disease and diphtheria. The mother contracted diphtheria alone.

Case CIX contracted diphtheria from Case VIII, which was one of laryngeal diphtheria.

Case CXV contracted diphtheria from Case CX, one of simple diphtheria of the fauces and palate. These four cases were placed in the same room in the hospital; the room had not had a case of scarlet fever in it for many months, and it had been thoroughly fumigated with sulphur and scrubbed with corrosive sublimate solution about once each month for a year. And yet Cases CIX and CXV, exposed to and suffering from diphtheria, were simultaneously attacked by scarlet fever. Both had albumin in the urine. Both desquamated. Case CIX died of suppurative nephritis, having apparently entirely convalesced from both his diphtheria and scarlet fever. I have included this death in the series of cases herewith reported as due to diphtheria.

These clinical testimonies to the apparent relationship or affinity of the two disease-processes might be multiplied, but multiplication of this simple testimony does not elucidate anything. May we not hope that careful and systematic bacteriologic study of cases may yet enable us to understand the rationale of the relationship, and simplify diagnosis, treatment, and prevention?

THE IDENTITY OF MEMBRANOUS CROUP AND LARYNGEAL DIPHTHERIA.

The lessening frequency with which membraneous croup appears in our mortality reports seems to indicate that this disease is either dying out or that practitioners are calling the condition formerly so designated by another name.

In all of my professional work, as student, as hospital resident and as practitioner, it has never been my fortune to see, either in my own practice or in that of my professional friends, a case that I could call one of membranous croup, *i. e.*, a non-infecting stenosis of the larynx, due to membrane-formation, as it is described in the text-books. I have seen cases that were called membranous croup, but with the diagnosis of which I did not and could not agree. The following cases are cited as examples:

Case I.—A young man now twenty years old. Every slight cold affects his throat. He has frequent attacks of tonsillitis and occasionally laryngitis of a catarrhal nature. His parents state that he had frequent attacks of greater severity in his

earlier years, accompanied by a "croupy cough." He would sit down to a meal feeling perfectly well; an attack would come on while he was eating; and he would almost die. Dr. W—— said it was membranous croup, and often he arrived just in time to save Harry's life. This is a case in which the patient's present condition offers a lucid explanation of the frequently recurring attacks of "membranous croup" in his earlier years.

He was finally cured of his "membranous croup" by the frequent administration of a home-remedy containing alum, sulphur, and molasses.

Case II.—A child three years old, seen in consultation with Dr. Bryant. It had a slight cold, and was suddenly taken with difficult, "crowing" respiration, rough, croupy cough, the ribs drawn in and the interspaces not filling out.

In this case the symptoms seemed typical of what is ordinarily called membranous croup, and tracheotomy seemed inevitable. Small fine râles were discovered all over both lungs, and inhalations of water vapor and of slaking lime seemed to relieve the difficulty of breathing, so that operative procedures were postponed for a day.

At the end of this time the laryngeal symptoms had greatly ameliorated, and disappeared entirely after a few days. No membrane was ever expectorated, but there was considerable bronchitis, with mucous expectoration. The case was plainly one of catarrhal laryngitis, and our diagnosis of membrane obstructing the larynx was premature and a mistake.

Case III occurred in a child just removed from a day-nursery, where it had been in the same room with four other children, all of whom had been attacked with diphtheria, and all of whom died. Two of the four had membrane in the larynx as well as in the fauces, and the other two had nasal involvement. This case, the fifth child, was suddenly seized with laryngeal symptoms and died after a very short illness. The attending physician certified the cause of death to be membranous croup. It seems to me almost certain, when I consider the intimate association of the patient with the four fatal cases, and its death in a few days after theirs, that the real case of death was laryngeal diphtheria.

Case IV.—The first of the four fatal cases referred to as being removed from the day-nursery. The attending physician informed the board of managers of the institution that it was suffering from membranous croup, and they, in consequence, were greatly amused at the precautions taken by the Health Department to prevent the spread of the disease. The patient came under my care at quarantine, and was a typical case of diphtheria. The membrane involved the fauces, palate, and larynx, and the child died after seventy-two hours' illness, having been tracheotomized six hours before death, which was due to heart-paralysis.

Case V.—A boy two years old was suddenly attacked one evening with difficult respiration and croupy cough, having complained for a day of what the parents regarded as a common cold. I was called hurriedly, and found the child black in the face and almost dead.

I was tempted to tracheotomize at once, but the subcutaneous injection of apomorphine caused prompt emesis, and the child's respiration improved. Turpeth mineral and calomel were administered in one-grain doses every fifteen minutes; the vomiting continued, the spasm of the larynx relaxed, and he became much better. The throat was carefully examined, and no membrane could be detected; but in spite of this the child seemed critically ill. The next day examination revealed a typical diphtheric membrane that had appeared since the preceding evening and covered both tonsils. It spread rapidly, covered the palate and advanced into the nose. For five days the little patient's condition was extremely precarious; then improvement began, and the membrane entirely disappeared in thirteen days after the date of the original attack. After the first evening there was no apparent laryngeal involvement.

There can be no doubt that this case presented all the classical symptoms of membranous croup the evening it was first attacked, and if death had occurred (and it seemed imminent), most practitioners would have certified to that as the cause of death. The subsequent history of the case, however, showed that the initial attack of laryngitis was probably only functional, occurring as the ushering-in symptom of an attack of diphtheria.

Case VI.—A child, aged one and a half years, a brother of Case LI, which died two weeks previously. Another sister had also died of a most pernicious form of diphtheria one week before. This babe was nursed by its mother, who was also nurse for the two children who died. It was taken ill, and died in twenty-four hours of so-called "membranous croup."

Case VII.—Into a house next to one in which diphtheria occurred one year ago, the premises of both being in a very filthy condition, a new family moves. After a week one child is taken sick and dies in twenty-four hours with what the physician calls "pseudo-membranous laryngitis." The same day a second child is taken ill with the same complaint, and dies in thirty-six hours. In the second case there is membrane visible in the fauces. The physician calls it "contagious membranous laryngitis" but says it is not diphtheria, although he regards it as being "quite as contagious as diphtheria."

Cases similar to the last two might be multiplied almost indefinitely from the records of the Health Department; a death from "membranous croup" being reported immediately before or immediately after several cases of diphtheria have occured in the same house or in an intimately associated family. Perhaps these occurrences only emphasize the cautionary admonition of Cohen and Eshner in their recent work on medical diagnosis, that "until a physician acquires considerable experience he had best consider all cases of membranous croup as diphtheritic." Yet, in my experience, older practitioners more frequently than younger ones pronounce laryngeal diphtheria to be "croup," and I am inclined to

regard the admonition quoted as catering too much to the fallacious belief which dignifies a symptom with the individuality of a disease.

One may not absolutely deny the possible existence of a non-infectious membranous laryngitis, for the condition would be a parallel one to that which exists in membranous bronchitis and enteritis. These diseases are, however, wonderfully rare, while the majority of believers in membranous croup rate it as a comparatively common disease.

Very recently Fraenkel published a paper detailing the results of autopsies on four cases of so-called primary or non-infectious membranous croup. In all, the mucous membrane of the pharynx and tonsils was intact, the disease-process being limited to the larynx, and in all the laryngeal membrane was found to contain the Klebs-Loeffler bacillus, the identity of which was proved, first, by staining, second, by culture-experiments, and, third, by the inoculation of animals. Still later, Martin of Paris found the Loeffler bacillus in 21 of 34 cases of croup, in which there was no membrane in the fauces. *Query:* Were the other 13 non-diphtheric?

Very important, as bearing on this particular point, is Prudden's case: One child died of a disease pronounced by the attending physician to be "croup, and not diphtheria," and Prudden himself failed to find either the bacillus or streptococcus of diphtheria in the membranes. However, a few days later, a second child of the same family died, presenting all the constitutional and local signs of diphtheria, "and the streptococci were found, not only in the membrane but in the viscera." Even the failure to find the diphtheria-germ in all cases is thus shown to be not positive or final testimony as to the non-contagious character of the disease; clinical evidence is equally important, and is very properly a supplement to, or supplemented by, bacteriologic investigation.

THE RELATIONSHIP OF DIPHTHERIA AND FOLLICULAR TONSILLITIS.

Occasionally that common and readily-identified disease, follicular tonsillitis, occurs epidemically and in a somewhat modified form. It has been asserted that when it so occurs it is really diphtheria. It would seem that there could be but one method of settling this question, namely, by bacteriologic examination of a large number of such cases. The type of follicular tonsillitis is so common and so readily studied, that it is a matter of some surprise that such an investigation has not already been made.

Clinical arguments against the supposed identity of the two conditions are, however, almost conclusive. In families or in institutions in which follicular tonsillitis prevails, all the cases are follicular; none develops extensive membrane; the nose is never involved; none of the patients dies. It is possible for a patient with this disease to be seriously sick, but the febrile conditions are almost constant in their occurrence and relationship; high temperature for a day or two is common, and it accompanies a full, bounding, rapid pulse; delirium may be coincident; when the febrile conditions subside they do so by crisis; circulation and temperature return to the normal at once and together. What a contrast to the progress and relationship of the febrile conditions, as already described, existing in diphtheria?

Of course, it is possible for diphtheric infection to be added to a previously existing follicular tonsillitis, but in such a case the clinical picture will change quickly, and it will always be noted that any immediately succeeding cases are typically diphtheric, both in incipiency and in progress. The follicular feature does not persist and manifest itself in subsequent cases after real diphtheria has made its appearance.

The deposit of follicular tonsillitis is a secretion, modified and unhealthy, perhaps, but still a secretion, and hence readily removed without harm to the underlying tissues. In sharp contrast is the diphtheric membrane, which is a fibrinous exudate upon a previously eroded surface, from which it cannot be removed without violence.

This distinguishing feature is all-important in the diagnosis, which is rarely difficult. If real doubt exist, twelve or twenty-four hours at most will suffice to clear it up. However, the fictitious credit attaching itself to the supposed rapid "cure" of cases of this kind has proved a strong incentive to some practitioners to pronounce as diphtheria all cases of follicular tonsillitis. This practice is most common in communities in which cases are not reported to the health-officers, and in which the premises are not placarded, and no quarantine is enforced.

A last argument against their identity is this: The diphtheric membrane ordinarily begins at one spot or location, from which, as a center, it spreads with a rapidity that is often alarming. Given a dozen or more foci (as would be the case if each follicle in the tonsil were a center from which the membrane could spread), and the rapidity of extension would be astounding. This would, indeed, be the most terrible and fatal form of diphtheria, by reason of the favorable circumstances attending its incipiency.

But the facts show that follicular tonsillitis is so seldom fatal that we may really say that it never kills, unless there exists some peculiar cachexia or other modifying condition of the patient.

The question of the identity of diphtheria and follicular tonsillitis may then be dismissed as unworthy of serious consideration.

(To be concluded.)

NEUROTIC ECZEMA.[1]

BY CUTHBERT R. BARHAM, M.D.,
FELLOW OF PITTSBURG ACADEMY OF MEDICINE, PITTSBURG.

IN the *Medical Record* of July 9, 1892, I published an article entitled, "A Study of Neurotic Eczema in Adults." The manuscript of that paper was placed in the hands of the publishers in March, 1892. Since that time I have continued my work and investigations upon this subject, and have been led to elaborate in some instances, and in many important particulars to change my views as formerly expressed regarding the etiology of this division of eczema.

The study of the relation of nervous disturbances to affections of the skin is not of recent origin, though systematic investigation in this direction has, so far, been undertaken by only a few dermatologists. Various authorities have indeed referred, at intervals, to the evidences of such relation, but in many cases only a reference was made. Among the pioneers may be mentioned Purdon,[2] Bastard,[3] Marracci[4] and Colominatti,[5] who in the years 1878 and 1879 reported cases of eczema in which various disturbances of the nervous system, or nerve-lesions, preceeded or accompanied the eruption, which seemed to depend on it.

Hebra taught that among other causes of eczema "faulty innervation" was often to be considered; Kaposi, that under certain circumstances, eczema must be considered as *neuropathic*. Wilson gave *nutritive and nervous debility* as a predisposing cause. Schwimmer, in his monograph, *Die Neuropathischen Dermatonosen*, 1885, seems to take the ground that the majority of cases of eczema depend on trophoneurotic disturbance. Kopp, on the other hand, in a monograph entitled *Die Trophoneurosen der Haut*, 1886, denies tropho-neurotic influence and is inclined to ascribe all eczematous eruptions to external irritation.

Crocker refers to vasomotor influence in an indefinite way as a probable cause of occasional eczema. Bulkley,[6] in his article, "Relation of Eczema to Disturbance of the Nervous System," ascribes many cases of eczema to "nervous disturbance."

Elliot[7] read a paper before the last meeting of the American Medical Association, in which he gave the name *reflex neurotic eczema* to a certain type of eczema occurring in babies and young children. He pointed out in this eruption peculiarities in location, grouping of the lesions, and course of the disease which are constant and which point to reflex nervous disturbance as the cause of the eruption. This, I think, is the first instance in which a variety of eczema has been isolated and described under the title of "neurotic."

In the cases related in this paper there are certain peculiarities of location, arrangement of individual lesions, and course of the eruption, which, together with the accompanying nervous disturbance and exclusion of external irritation, seem to warrant the recognition of a neurotic eczema.

It is the purpose of this paper to prove its existence as a distinct subdivision of eczema; to point out the character of the lesions and to state the grounds upon which the classification is advocated.

The discussion of a few typical cases may lead to a better appreciation of the subject. Owing to the length of the histories only the important features will be mentioned.[1]

CASE I.—Female servant, aged fifty-five, passed the climacteric five years ago; among other disorders connected with this period, had an eruption on the face, similar, as she stated, to that now evident. It disappeared after four weeks' duration. She has been free from eruptions of any kind until eighteen months ago. Six months previously to the present outbreak the patient returned to Ireland, and during the journey and stay was subjected to exposure and a great deal of mental worry on account of death in her family and other troubles. She also contracted malaria while there, and has had frequent malarial attacks since her return; at such times she is unusually constipated and suffers from insomnia and nervousness. The eruption is worse after these attacks. The appetite and digestion are good. Constipation is present at all times.

The eruption is situated on the lower two-thirds of the forearms and legs, and is rather more distinctly shown on the extensor than on the flexor surfaces, on the upper surfaces of the hands and feet, and is symmetrical.

The eruption is characterized by patches, circular or round in shape, and composed of vesicles or papules (or both) with intervals of healthy skin. The patches show all stages of inflammation, from unbroken vesicles and papules to raw exuding surfaces, or infiltrated and covered with crusts or fine scales. Each patch is limited by a line of papules or vesicles, and the division between healthy and diseased skin is sharp and absolute. (In a few instances there were observed outlying papules, or groups of from three to ten, but in no case was there observed that gradual fading of the eruption around the periphery observed in eczema as ordinarily encountered.) At all stages of the disease the pruritus has been intense.

CASE II.—A male, a weaver, aged thirty-five,

[6] THE MEDICAL NEWS, January 31 and February 7, 1891.

[7] Int. Med. Mag., October, 1892.

[1] The cases given were taken from Dr. L. D. Bulkley's clinic at the New York Skin and Cancer Hospital, by permission of Dr. Geo. T. Elliot, under whose care they were.

no previous history obtained; suffered from constipation, obstinate and prolonged, and was "nervous and irritable." The eruption is located on the dorsum and interdigital spaces of the fingers and on the back of each wrist. Between the fingers the skin is sodden, but the inflammation is sharply defined at the edge of the patch. On the back of each wrist is a large, rounded, sharply-defined patch, moist and inflamed, the edges composed of vesicles and papules. The patch is infiltrated and the pruritus is excessive.

CASE III.—A male, longshoreman, aged thirty, with no previous history other than that the eruption has appeared at various times since childhood on his hands and legs, each time being symmetrical. His habits are irregular. He is constipated. The eruption is located on the backs of the hands, and consists of circumscribed patches formed of papules and vesicles closely aggregated. Some are irritated and moist, others are crusted. It is absolutely symmetrical, and the pruritus is excessive. He improved under treatment, but left the clinic before a cure was effected. He returned in two months with "elevated and inflamed moist patches, symmetrically situated along the ulnar border of the forearms and back of the hands." He remained at the clinic until discharged cured, but returned again in two months[1] "with patches of all sizes and shapes more or less inflamed," on the extensor surface of the wrists, hands, and forearms.

CASE IV.—Female, a servant, aged forty-three, without previous history. Constipation and nervousness are noted. The eruption is located on the extensor surface of the hands and wrists, and lately on the extensor surface of the legs. The eruption is characterized by groups of papules and vesicles of various sizes, forming patches, circular in the main, with sharply-defined edges, moist and irritated in character.

CASE V.—Male, a surveyor, aged twenty-four, who is out of doors on duty most of the time. His stomach is irritable, and he has to eat cold food, which brings on attacks of indigestion and increases his nervousness. He has not been free from the eruption for the past year. He has obstinate constipation, occasional indigestion, and nervousness. The eruption is on the cheeks and forehead, and there is a circumscribed patch on each cheek, 1½ inches in diameter, composed of closely aggregated papules, sharply defined. On the forehead are a number of similar circumscribed patches, containing from ten to thirty papules.

CASE VI.—A female, married, aged thirty-eight. The eruption has been present for ten years. She has complained of a tired listless feeling for some time. She is anemic, nervous, and has been constipated for a long time. The eruption is located on the cheeks and forehead, each cheek presenting a large circumscribed patch composed of thickly-set papules, with considerable thickening and scaling. On the forehead are a number of similar patches presenting the same characters as those on the cheeks, though there is less thickening of the skin.

[1] Dr. Geo. T. Elliot's notes, made from his record of this case.

CASE VII.—A male, a pauper, aged sixty-three. Until five years ago the patient was a fairly prosperous broker, when he lost all his property in speculation. He has no relatives living, and since then he has been dependent on charity. His health is wrecked, and he presents many symptoms of disseminated sclerosis of the cord. The outbreak of the eruption was preceded by great mental anxiety. He also has constipation. The eruption is located over the deltoid region, on the extensor surfaces of the arms and forearms, on the front of the thighs and knees, and around the circumference of the legs, being rather more marked on the extensor than on the flexor surfaces. There are patches composed of thickly set papules, circumscribed, scattered over the surface named, dry and scaling in character. The pruritis is intense.

CASE VIII.—A schoolboy, aged thirteen, has had eruptions since early childhood. He suffers from asthma when near the seashore, at which time the eruption is worse. His general health is excellent, and he has no constipation. The eruption is on the cheeks, the extensor surfaces of the arms and forearms, the front of the thighs and *back* of the legs. The patches are more or less circular, sharply defined, moist or scaling, or simply formed of papules in the primary stage, according to duration.

In the foregoing histories the following points seem worthy of note:

1st. The most striking peculiarity is the symmetrical disposition of the lesions. In many cases the symmetry is absolute, in others approximate, but in every case corresponding parts of the body on each side are found to be affected.

2d. The eruption tends to attack localities not as a rule liable to eczema in its primary state, *i. e.*, the extensor surface of the extremities.

3d. The arrangement of the lesions differs markedly from that usually observed in eczema. The lesions are not scattered indiscriminately over the affected area, but are grouped into patches, which are more or less circular. These patches are composed of closely aggregated papules and vesicles; the edges are sharply defined, and usually made up of a line of papules or vesicles. The periphery remains distinct, sharply defined, and absolute at all stages.

4th. The spread of the eruption is never affected by a gradual extension of the area of the diseased patches, but by the formation of new lesions or patches, in every respect retaining the characteristics of the older ones.

5th. The dissolution of a patch is accomplished not by a gradual shrinking of the diseased area, but by a decrease of inflammation, the original area remaining the same in extent.

6th. The eruption has a tendency to frequent relapses, for which often no adequate cause can be ascertained, and this in spite of the most careful attention.

7th. The pruritus is most intense.

Before entering upon a discussion of the etiology it may be well to give a short *résumé*.

1st. Previous, mental worry or nervous exhaustion of longer or shorter duration is noted in Cases I, II, IV, V, VI, and VII. (Insomnia and "nervousness" or "irritability" are included under this head.)

2d. Various functional irregularities and chronic constipation are noted in Cases I, II, III, IV, V, VI, and VII. Occasional indigestion in Case V.

3d. Complications: Asthma is noted in Case VIII; multiple sclerosis in Case VII; malaria in Case I; anemia in Case VI.

4th. External irritating conditions: Exposure to heat and cold in Cases III and V; exposure to irritating soaps and alkalies, presumably from occupation, in Cases I, IV, V, and VI.

5th. Locations attacked: Face, in Cases V, VI, and VIII; extensor surfaces of hands, wrists or arms, Cases I, II, III, IV, VII, and VIII; extensor surfaces of legs, thighs or feet, etc., Cases I, III, (previously IV, VII, and VIII); flexor surfaces, in Cases I, VII, and VIII, leg. (In each case, with the exception of Case VIII, after appearing on the extensor surfaces).

In studying this *résumé* we are impressed by the facts that in only three instances were the flexor surfaces involved; in two of these slightly; and that in *all* of the cases the eruption appeared here after first appearing on the extensor surfaces. In some other instances the eruption appears on surfaces liable to irritation from various causes, but in only a small number of these was there a history of exposure to such influences.

Considering external influences somewhat in detail, we find that Cases III and V were exposed to ordinary variations of heat and cold incident to an out-door life; so that the evidence of their influence here is not conclusive, probably serving only as of irritation after the eruption commenced, sources and hence should not be properly considered causative.

In Cases I, IV, and VI there was, from the nature of the occupation, presumable exposure to moisture, irritating soaps and alkalies, and in two of these (I and IV) the eruption appeared on parts naturally exposed to the action of such agents. But on examining the lesions we find that the appearance is not that usually presented by an irritative eczema. In no case is the palm involved, and in only one case (I) the flexor surface, and here it appears after being established on the extensor surface. Moreover, there is a tendency for the lesions to appear in separate and sharply defined *patches*, with intervals of healthy skin. This would not be the case were external irritation an important factor in the etiology, but instead we should have a more or less papular or vesicular eruption over the whole surface so exposed. In Case VI the question of external influence may be dismissed with the observation that the parts exposed to irritating agencies were not involved, but the face instead. I think, therefore, we may exclude external conditions as a factor in the production of this eruption, and give them prominence only as complicating, by irritation, after its establishment.

Of the functional irregularities, the most frequent was indigestion or irritability of the stomach, which was found in two instances. Whatever influence may be exerted by this condition must be reflex, and, except in chronic indigestion, is not of sufficiently long duration to cause the morbid changes seen in eczema. On the other hand it will readily be admitted that its influence is powerful after the establishment of the eruption, when the hypersensitive nerves and nerve-centers easily respond to a very slight stimulus.

Chronic constipation was noted in seven of the eight cases, and is probably a fruitful cause of the disturbance. Theoretically we may explain this action in one of two ways.

1. By reflex irritation, or 2, by irritation of both the central nervous system and peripheral nerves, in consequence of the retention in the blood of irritating alkaloids or products of digestion.

Asthma was noted in one instance, Case VIII, but as to its influence I am in doubt. It has long been noticed that this affection occasionally occurs as a complication of eczema, but as yet no satisfactory explanation has been offered. Similarity in etiology probably exists.

Multiple sclerosis is noted in only one Case (VII), and though I hesitate to ascribe too much importance to its influence, I am forced to believe that it is of some weight. The case in question was extremely obstinate, and resisted all treatment. It is very probable that the sclerosed papules acted as local irritants to adjacent portions of the cord. The significance of this irritation is shown by the theories promulgated in Gowers's work concerning the trophic functions of the cord in relation to the skin, *i. e.*, "it is probable that there is progressive representation (sensory) of the skin in the posterior nerve-cells of the cord." It is true that, as a rule, sensation is but slightly effected in multiple sclerosis; still these islands of sclerosed tissue may produce irritation in the posterior tracts, and thus render the sensory nerves more responsive to irritation. Gowers further states that the nutrition of the skin[1] "seems to depend on nerves which have their course in the posterior roots." Therefore, it seems

[1] Gowers: Manual of Diseases of the Nervous System. 1892.

probable that irritation in the posterior roots would produce trophic lesions in the skin which would be shown in the eczematous inflammation.

In addition to the multiple sclerosis, which may be considered rather as an interesting complication than a cause, there were certain functional irregularities.

Malaria was noted in one case (I), and, although this cannot be definitely isolated as a primary cause, it is certain that a symmetrical peripheral neuritis, whose pathology and symptoms are as yet but indefinitely recorded, may be due to such agents, organic or alkaloidal in character, as are contained in the blood in malaria.

This symmetrical peripheral neuritis is probably influential not only in the production of the lesions, but also in determining the location of the affection.

Anemia was found in only one case (VI). Its action, if any, is chiefly predisposing, not to eczema especially, but the debility consequent upon or leading to anemia necessarily lessens the resisting power of any tissue to irritation, local or reflex.

Previous mental anxiety or an existing state of nervous depression is found in the histories of six of the eight cases. Its importance cannot be overestimated. Bulkley[1] lays great stress on this point, and gives many clinical examples in which it is found to be a "predisposing element," or "exists in connection with other nervous conditions which act as the exciting cause of the eruption." Kopp admits the importance of this factor, but claims that it is chiefly predisposing. Gowers[2] referring to "spontaneous" sensations of the skin, such as itching, burning, tingling, etc., without visible lesion, classes them among the functional disturbances of the cord, and includes the very varied range of symptoms under the head of neurasthenia, which may be described as functional disease of the cord. There is enfeeblement of the general nervous system, and consequently impaired nutrition of the cord, from which follow perverted trophic functions and readier response to local or reflex irritation. In discussing the etiology of neurasthenia he says: "It should be remembered that mental anxiety is a potent cause of disease of the nervous system."

Now, eczema is an inflammation of the skin, and, as such, must be due to irritation. The irritation may ordinarily be accomplished in one or more of three ways.

1. By external conditions. 2. By direct action upon the tissues of noxious substances contained in the blood, either in the process of excretion or by being deposited in the tissues. 3. By action of the nerves supplied to the inflamed parts.

That it is not due to the first I think I have fairly demonstrated in the discussion of the *résumé* under the head of external influences. That it is not due to the second may be inferred from the grouped arrangement of the lesions, its symmetry of location, manner of spreading, and manner of healing. We have an example of eczema due to (presumably) direct action of noxious substances contained in the blood or the tissues. I refer to the so-called "gouty eczema," due to retention in the system of acids and from improper action of the kidneys. The spreading of this eczema takes place by peripheral extension, and healing occurs by noticeable peripheral contraction of a patch. Moreover, symmetry of location noticeable in neurotic eczema is rarely seen in gouty eczema.

For these reasons I ascribe to the variety under discussion a neurotic etiology. In considering this source of irritation we may examine in turn the various parts of the nervous system as follows:

1. Vasomotor or sympathetic system.
2. Sensory nerves and tracts of the cord.
3. The trophic centers of the cord, and
4. The reflex phenomena and their significance.

The part played by the vasomotor system is, I believe, mainly secondary. We may readily recognize disturbance in this quarter by the redness and slight swelling of the inflamed patches; yet evidence is lacking to show that simple dilatation or contraction of the bloodvessels, of however long duration, results in such permanent changes in the skin as we observe in eczema. In regard to the sympathetic system we have one report[1] of an autopsy from Prof. Michelani's clinic, in which, at the post-mortem of a patient suffering from universal eczema and who had died of pneumonia, "the upper cervical and celiac ganglia were fonnd markedly hyperemic, with cloudy swelling of the nerve-cells and marked pigmentation in the intercellular tissue."

As the same condition will be found in persons dying of pneumonia or typhoid fever, or in fact from any acute inflammation in parts situated near these ganglia, I fail to see that it is of much importance. At this time so little is known concerning the normal histology and physiology of the sympathetics that it would be unwise to speak decidedly for or against their influence. But as yet I see no reason to ascribe the eczematous eruption to their influence. The trophic centers for the skin, as before stated, seem to be situated in the posterior columns of the cord, or, according to Gowers, "the nutrition of the skin seems to depend on nerves which have their course in the posterior roots." It would probably be better to dismiss entirely the terms "trophic nerves and centers" and to accept the plausible

[1] THE MEDICAL NEWS, Jan. 31, 1891: "Relation of Eczema to Disturbance of the Nervous System."

[1] Morrocci: Giorn. Ital. delle Mal. della Pelle.

theory of this author, that "nerve-endings have a structural continuity with the tissues supplied by them," and hence that the nutrition of the tissue is determined in its character by that of the nerve. By accepting this theory we reduce our consideration to two points—the spinal cord and the sensory nerves.

In regard to the spinal cord, it has been conclusively shown that the nutrition of a nerve is presided over or governed by certain ganglia or centers at its root. Now, if it is shown that the proper action of these centers is interfered with or hindered in any way by certain conditions, whether by local inflammation or irritation from other points, it would necessarily follow that a trophic disturbance of greater or less intensity would follow in the course of the nerve. And as the tissues are practically continuations of the nerves, and the nutritional energy diminishes as the distance from centers increases,[1] it seems most probable that this trophic disturbance would evince itself in the tissues.

We have seen that mental worry or shock can and does cause this perverted functional action of the cord, and have clinical examples[2] before us of the occurrence of eczema in this connection; while instances are not wanting of eczema occurring as a result of local inflammation in the posterior columns of the cord and confined to areas supplied by certain nerves.[3]

In connection with the spinal cord we may consider reflex phenomena. Owing to our lack of accurate knowledge as to the physiology of *reflex* inflammation, our opinions as to this question must be purely theoretic. We have seen that a large number of the cases here reported were associated with chronic constipation; some with indigestion more or less chronic. It is a fact that with improvement or relapse of these conditions a corresponding improvement or exacerbation of the eruption was observed, though not in so great a degree. Elliot,[4] speaking of the neurotic eczema of children, which agrees with that one in older persons in many particulars, says: "I do not see how the symptoms in the skin could be explained except on that basis (reflex origin), where we observe the eruption responding immediately to the development of an irritation in a distant portion of the body; varying in degree according to the intensity and persistency of the irritation; agreeing in its evolution and involution accurately with the changes in the character of the latter; disappearing with its removal and relapsing with its recrudescence." The same is true in part of the variety here considered. In adults the variations are not so marked, and, when the source of reflex irritation is associated with functional nervous disorder the removal of the source of irritation regarded as reflex does not result in the disappearance of the eruption. In view of this fact I am inclined to believe that the results of reflex irritation and nervous exhaustion are the same in regard to their action on the cord, *i.e.*, both produce more or less irritation of the trophic centers which results in perverted functional action. Whether this irritation is an actual inflammation or not I am not prepared to state, but in results it is practically the same.

Should further investigation prove that inflammation does actually exist, then the significance of *reflex irritation* will be made plain.

In regard to the sensory nerves, their participation is shown by the intense itching present in the affected area from the beginning of the eruption. This feature, while it is only a complication, or a symptom, if you please, denotes, from its early occurrence, I think, either a primary affection of the sensory nerves or an irritation of the sensory centers, already mentioned, at an early stage of the disease.

I notice, in Gowers's work on *Nervous Diseases*, a description of a form of *multiple neuritis*, symmetrical in location, after the general type of lead poisoning which tends, by preference, to attack the nerves supplied to the extensor muscles and tissues covering them, and which, according to this author, is rare and always due to "a morbid blood-state having direct influence on nerve-tissue." This morbid blood-state seems to consist in the presence of some virus or organic substance to which the nerve-fibers are susceptible. Among these substances are malarial germs, products of constipation and indigestion (ptomaïnes, etc.), certain metallic poisons, etc., of which the first two classes are encountered among our cases. Various trophic disturbances follow and are apparently due to this neuritis, especially in the muscles, more rarely in the skin. This neuritis is not persistent after the cause is removed, but disappears in time, the nerve resuming nearly, if not quite, its normal condition, and the functional activity of the nerve is rarely entirely destroyed.

In 1879 Colomiatti[1] reported a number of cases of eczema in which, on microscopic examination there were found material changes in the nerves supplied to the affected parts; while in cases which had been cured he found the nerves nearly or quite restored to the original state. Leloir[2] was able to verify these statements in 1890.

[2] Annales de Dermat. et de Syph., 1890.

Now, as to the connection between neurotic eczema and multiple neuritis of this type I desire to point out a few points of interest. This neurotic eczema is rare, and is found often in connection with chronic constipation, sometimes with malaria, the same being true of the neuritis. The neuritis is symmetrical and tends to attack nerves supplied to extensor surfaces, while the lesions of neurotic eczema are symmetrical and tend to involve extensor surfaces. Pain, which is noted by Gowers, is absent in this form of eczema, but there is intense pruritis.[1]

The circumscribed character of the eczema is also strongly in favor of the theory that in some cases, at least, the peripheral inflammation of the nerve causes the trophic disturbances in the skin, and, consequently, only the parts supplied by this nerve are affected.

Schwimmer,[2] in discussing Colomiatti's report, makes the following comment: "Contributions of this kind demonstrate that a nerve-lesion may be followed directly by the eruption of eczema, which was formerly known only of erythema, urticaria, and herpetic eruptions;" also that "the nerve-fibers themselves show a process of degeneration in the course of eczema." As a similar degeneration is sometimes seen in nerves supplied to inflamed tissues, it remains in doubt whether the neuritis, when observed with eczema, "is due to the intensity of the inflammation in neighboring tissues,"[3] or whether the eczema is the result of the neuritis. From the fact that the neuritis often occurs independently of eczema I am inclined to the latter view, inasmuch as this offers some explanation for the location of the eruption on the extensor surface, while if the former were true it seems probable that the eruption would attack flexor surfaces instead. Moreover, the fact that the intense pruritis is present from the beginning is an argument in favor of the latter view.

From the foregoing study I have come to the following conclusions:

1. That there is a variety of eczema due to nervous disturbance, which may be recognized by the following characteristics:

a. Grouping of the lesions in circumscribed patches, sharply separated from adjoining healthy skin.

b. Symmetry of the eruption as a whole.

c. Preference for the extensor surfaces of the extremities.

d. Absence of peripheral spreading or contraction of the separate patches.

2. That the nervous disturbance is a perverted functional action of the "trophic centers" in the cord; and probably in some cases a peripheral neuritis.

3. That reflex irritation—from various functional irregularities, mental anxiety, neurasthenia, etc.—are important predisposing factors.

AIDS TO THE ADOPTION OF THE METRIC SYSTEM IN PRESCRIPTION-WRITING.

BY ELI H. LONG, M.D.,
ADJUNCT PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, UNIVERSITY OF BUFFALO; PROFESSOR OF MATERIA MEDICA, BUFFALO COLLEGE OF PHARMACY.

THE question of the practical use of the metric system by physicians is coming at the present time to assume considerable importance. We are upon the eve of the issue of the new United States Pharmacopeia, in which all quantities will be expressed in metric terms, a feature that was adopted after full and free discussion by the representative physicians and pharmacists who composed the pharmacopeial convention. This step in advance will never be retraced; therefore, the sooner we take our stand accordingly the better.

Enough has been said in discussion of the new system, and the verdict seems to be that it is unquestionably superior to any other, mainly because it is simpler. This paper, therefore, takes for granted the desirability of its more general use, and aims to meet practically some of the difficulties and objections that stand in the way of its adoption.

The chief difficulty lies in the fact that we do our thinking in the system of weights and measures most familiar to us, so that all, except those who have early and thoroughly learned the metric system, must practically do their calculating for a time in the old system. The practical American sees little utility in a system that requires a mental translation at every turn; hence the indifference to the superiority of the metric system among the members of our profession.

I am convinced that in order to meet this difficulty we must simplify the relation between the two systems so as to reduce to a minimum the necessity of translation and calculation. And so effectually can this be done that to master the application of the metric system to prescription-writing need be a matter only of a very few moments' thought, even to those who have employed the old system for years. The plan here given has, by extensive use in class-work, been found fully adequate.

We begin by making the number of doses in our prescription correspond with the number of grains

in a gram. As there are between *fifteen* and *sixteen* grains in a gram, either of these numbers[1] can represent the whole number of doses. This being determined, we find that the *same figure* that expresses the *single dose* of any ingredient *in grains* expresses also its *total quantity* in *grams*. The following will illustrate this, the same rule obtaining as well with *minims* as with *cubic centimeters*:

	Grams or c. c.
R.—Potassii bromidi (single dose 10 grains)	10
Morphinæ sulphatis (single dose ¼ grain)	25
Spiritus ætheris nitrosi (single dose 30 minims)	30
Aquæ q. s. ad (16 teaspoonful doses)	60
M. Sig., etc.	

Observing the cardinal rule that the number of doses shall equal the number of grains in a gram, or of minims in a cubic centimeter, we find that sixteen 10-grain doses amount to about 10 grams; sixteen ¼-grain doses amount to about ¼ or 0.25 of a gram; sixteen 30-minim doses amount to about 30 cubic centimeters. When the single dose is a fraction of a grain the latter requires simply to be expressed in decimal form under the same rule.

The simplicity of the plan appears at once. It is necessary only to determine the single dose of any ingredient in grains or minims and write the number down as expressing the whole quantity in grams or cubic centimeters. It follows that, instead of being a difficult system to use, the metric system requires much less effort than writing according to the old system, for the reason that calculation and multiplication of doses are entirely done away with.

Sixteen doses are quite sufficient in most cases for one prescription, and the quantity of the dose, whether a teaspoonful, a dessertspoonful, or a tablespoonful, is immaterial so long as the number of doses is the same. If, however, it is desired to order twice the number of doses, it simply requires to double the number expressing the quantity in case of each ingredient; or, if half the number of doses is wanted, to order one-half of the quantities which the rule would give.

Another objection sometimes offered is that the bottles in present use are not of proper sizes for convenient metric quantities. But the plan here advanced would exactly suit the present sizes of bottles; thus, sixteen teaspoonful doses will make two fluidounces; sixteen dessertspoonfuls, four fluidounces, and sixteen tablespoonfuls, eight fluidounces.

In prescribing powders or pills the same rule applies as for fluids, for example:

	Grams or c. c.
R.—Pulveris ipecacuanhæ et opii (single dose 5 grains)	5
Pulveris digitalis (single dose 1 grain)	1
Strychninæ sulphatis (single dose $\frac{1}{50}$ grain)	02
Misce et divide in chartulas numero xvj.	

[1] One gram equals 15.43 grains, while one cubic centimeter measures 16.23 minims. Therefore, if one number is adopted for both liquids and solids, 16 is the better one. In case of ordering pills, powders, or other solids, 15 would be more nearly accurate.

The ordering of fifteen or sixteen doses always establishes the relation between the two systems, which permits us to apply the rule that has been demonstrated and which may be fully stated thus:

1. *Make the whole quantity to consist of sixteen doses;* then, 2. *The number that represents the single dose of an ingredient in grains or minims will express the required quantity of that ingredient in grams or cubic centimeters.*

It may be objected to this rule that it does not render one independent of the old system. This is true at first, but in learning a new system of any kind the most effectual way is to come practically into contact with it. This is what we accomplish by thus linking the two systems together, and the result must be that we soon acquire a familiarity with the simpler, new system, and the ability to use it independently will be only a matter of time.

Another objection to the use of the metric system, one that may be valid as applied to some sections, but which must be regarded as much an excuse as an objection when applied to cities, is that some risk of error is incurred on account of dispensing pharmacists being unfamiliar with the system. This objection is met by the fact that the handbook of the pharmacist, the new United States Pharmacopeia, is to employ the metric system exclusively, which fact gives evidence that the pharmacal profession is fully abreast, if not in advance of the medical, in respect to the matter under consideration; otherwise the Pharmacopeia would hardly show this advance. Indeed, if the comparison be a fair one, we shall find among representative pharmacists and physicians more pharmacists than physicians practically conversant with the metric system.

Therefore, and in cities especially, no one need fear to send a prescription in metric terms to any *first-class* pharmacy.

CLINICAL MEMORANDA.

REPORT OF THE TREATMENT OF A CASE OF FRACTURE OF THE FEMUR DURING DELIVERY.

BY LEROY W. HUBBARD, A.M., M.D.,
OF NEW YORK CITY.

IF we judge from the published reports of cases, we must conclude that fracture of the femur during delivery is a rare accident in obstetrics. I have been unable to find reports of more than three cases, and all of these occurred during the present century.

The first case was that of J. H. Vander Veer.[1] The child was extremely large, weighing fourteen pounds, and presented by the breech. The left thigh was bent back and sideways in the uterus. The delivery seems to have

[1] N. Y. Journ. of Med., 1847, vol. viii, p. 378.

occurred without much interference on the part of the physician and without accident except cessation of pulsation in the cord due to retention of the head. After delivery it was noticed that the left thigh was motionless, and an examination showed a false point of motion without crepitus.

The method of treatment is not given in detail, but nine days after delivery, the inflammation and swelling had increased very much, the bandages were loose owing to constant motion, and the thigh was flexed or semiflexed on the abomen. As to the result, "the union was better than expected."

In Dr. Jas. Young's[1] case the fracture was not discovered for two weeks after delivery, and then only because continual crying on the part of the child led to an examination. Pasteboard splints were applied and kept on for six weeks. The comment was: "Rare and troublesome case and difficult to keep clean." As to the final result nothing is said. This case was a perfectly normal delivery, the head presenting, and the pertinent question is asked: "How was the leg fractured, and when?"

Dr. E. N. Chapman[2] reports a case that also occurred in a normal labor. The fracture was at the junction of the upper and middle thirds of the thigh, and crepitation was present. He employed a sole-leather splint, which was kept on for fourteen days, and the result seems to have been good, for he reports "no shortening, and difficult to locate the fracture."

The fact that the femur may be fractured in a normal labor and that the accident can occur quite easily in a breech-presentation when even precaution is taken, may perhaps be sufficient reason for presenting a short report of a case. I am further influenced by the statements of two of the gentlemen who reported their cases, that it was exceedingly difficult to keep the fragments in apposition and to keep the child clean.

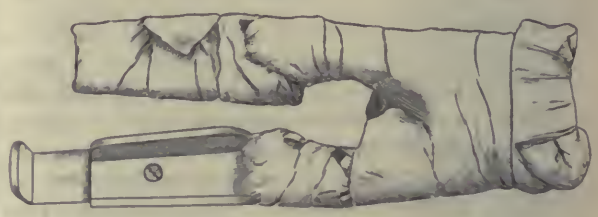
On June 15th, 1892, I was requested by a colleague in a neighboring city to see with him, in consultation, a baby who had been born the day before with a fractured thigh.

I made an appointment for the following day, and then began to study a plan of treatment. Realizing the difficulty, as expressed by the gentlemen quoted, of applying to a child of that age extension or coaptation splints which could be kept in place or would not become so readily soiled as to make frequent change necessary, I was for some time puzzled.

During my service at Bellevue Hospital I had treated a fractured thigh in a baby a few weeks old by placing it upon a board and making extension by means of adhesive plaster and rubber bands. The result was excellent, and during the treatment it was quite easy to keep the child clean. I determined to try the same method in this case, with some modifications. Keeping in mind the approximate size of a newborn child, I cut out a pattern and took it to a carpenter, who made under my direction an apparatus illustrated herewith in Figs. 1 and 2. The main part consisted of a piece of half-inch board, cut in shape resembling the trunk and lower limbs of a child. Upon the edges of each extremity narrow strips were fastened, making shallow troughs, and to each was attached a sliding foot-piece which could be regulated by means of a thumb-screw.

On the following day I saw my patient, a healthy, well-formed, vigorous boy—in consultation with the family physician. The mother, a primipara, had carried the child to full term, the breech presented, and the labor being prolonged with prolapse of the cord, which ceased to pulsate, it was necessary to extract the child somewhat rapidly. Apparently no undue force was used, but my friend discovered after delivery that the left thigh had sustained a fracture at the junction of the upper and middle thirds.

FIG. 1.



Examination showed the thigh to be swollen, the flesh being hard and tense. When undisturbed, the child lay with the limb drawn up in a position of flexion, abduction, and external rotation, and was quiet; but any attempt to move it evidently caused pain and was met with a muscular resistance which was remarkable in a child of that age. There was marked deformity and a false point of motion, but no crepitus. By making steady traction on the lower portion of the thigh, the body being firmly held, the muscular resistance was gradually overcome and the limb could be placed in a good position. When this was accomplished the child ceased crying.

FIG. 2.

The body and thigh portions of the apparatus were now thickly padded with cotton held in place by turns of a roller bandage, and I then applied to the leg and thigh below the seat of fracture two narrow strips of rubber adhesive plaster, and to the lower end of each attaching a loop of stout cord; the whole being held in place by a roller bandage carefully stitched. The baby was then placed upon the board and the body firmly secured to it by a bandage, and the leg troughs thickly padded with cotton. Through each loop of cord I passed double a rubber elastic band used by stationers, and slipped the double end over a screw in the upright of the sliding foot-piece. By drawing this down and fastening it with the thumb-screw the fragments could be brought into apposition and held there by elastic tension, in case the body of the child slipped any. For additional security and to keep the ends of the bone from riding up, owing to the vigorous movements of the child, a strip of plaster was carried over the thigh and the whole limb secured

[1] Trans. Edinburgh Obstet. Soc., 1875, 3, 127.
[2] Med. and Surg. Reporter, Phila., vol. ix, 329.

by a bandage. The uninjured limb was fastened to the other leg-piece to keep it out of the way. Fig. 3 shows the child in the apparatus. As soon as the dressing was completed he ceased to cry, became quiet, and soon contentedly nursed.

During the whole course of treatment he could be easily handled, the dressing did not become soiled with the discharges, and it was very little more trouble to take care of him than of any baby of that age. In spite of the facts that he was jaundiced, was not washed for three weeks, and that the weather most of the time was hot, he ate and slept well, thrived, and actually grew fat. It was necessary to readjust the body bandages two or three

FIG. 3.

times, owing to the wriggling of the child, and once, I believe, the family physician loosened the strip of plaster over the thigh on account of swelling. At the end of three weeks the apparatus was removed and union was found to be quite firm. There was no excoriation from the plaster or from pressure. There was a large amount of callus, but no shortening.

When I saw the child again, in August, the callus had nearly disappeared, the limb was straight, no shortening had taken place, and the union was very firm.

This method commends itself in the treatment of all fractures of the thigh in very young children, for the following reasons:

1. It is easy to reduce the deformity and keep it reduced, with the fragments in good apposition.

2. Frequent changes of dressing are not required, thus securing rest to the injured parts.

3. The apparatus and dressings can be easily kept clean, and the child can be cared for with very little more trouble than any normal and healthy child.

4. It can be quickly constructed, and its cheapness brings it within reach of all.

326 LENOX AVENUE.

GONORRHEA OF THE RECTUM.

BY GEORGE DOCK, M.D.,
PROFESSSOR OF THEORY AND PRACTICE OF MEDICINE AND CLINICAL MEDICINE IN THE UNIVERSITY OF MICHIGAN, ANN ARBOR, MICH.

THE existence of gonorrhea of the rectum, admitted to be a rare disease by most writers, has been denied by others. Since the discovery of the gonococcus of Neisser (1879) only one case has been recorded in which that organism was found in the rectal discharges. (Frisch, *Mitth. aus der Syph. Klinik zu Würzburg*, xxv, 1891; also in Virchow-Hirsch's *Jahresbericht*, ii, 1891, 552, and *Centralbl. f. Bakt. u. Parasit.*, i, 1892, p. 11.) Other cases, not necessary to cite, have been published, without an examination of the pus, but their true gonorrheal nature has been questioned.

A good deal of the skepticism with regard to gonorrhea of the rectum is no doubt due to the ideas of some of the older writers, which have been handed down without criticism by later ones. Evidently the whole subject must be studied objectively in the light of bacteriology and, if possible, also by experiments. In the meantime, the account of a single case, even if imperfect, may do good in calling attention to the subject, and it is for this reason that I report the following:

J. P., twenty-five years old, a barber, applied at the medical clinic of the University Hospital for the treatment of spermatorrhea. The patient stated that he had had gonorrhea three years before, but that after some months the discharge ceased entirely. For a long time he believed that he had spermatorrhea, a belief probably kept up by some of the "doctors" consulted. During the ten weeks just before admission he consulted and was treated more or less by six different practitioners. The last coitus took place eight weeks before admission. Six weeks after that he began a bougie-cure for impotence, using at the same time rectal suppositories as part of the treatment. After the sound was passed the third time a muco-purulent discharge appeared at the meatus urinarius and continued up to and after admission. This was accompanied by the usual symptoms of mild gonorrhea.

The pus contained considerable numbers of gonococci having the usual morphologic and tinctorial characteristics.

Repeated examinations showed the absence of spermatorrhea, and we were about to send the patient back to his physician at home when the rectal complication was discovered.

Feeling an inclination to stool, the patient went to the closet. There he passed a few drops of watery matter, part of which he brought to my laboratory. This was examined by my assistant, Dr. Whinery, who found gonococci. This led to a careful inquiry into the history as given (some of the statements of which had been looked on with natural distrust when first given), and to a rectal examination. Although the patient had an unusual sensation in the rectum, he had not attributed much importance to it, and it is probable that had he not seen the pus no examination would have been made.

On examining the rectum by means of a bivalve speculum I found intense redness and swelling of the mucous membrane as far as the instrument reached, a distance of about four inches. The surface of the mucous membrane was finely granular, without ulcers or erosions. The inflammatory process was sharply limited in a zigzag line at the margin of the epidermic part of the anus. In the folds were masses of pus, most of them small, and in the collapsed part, just above the end of the speculum, was about half a dram of pus and mucus.

Microscopically, the pus showed the ordinary polynuclear leukocytes, with a small proportion of eosinophilous cells. It contained large numbers of diplococci, identical in size and form with those in the urethral pus and in that from other cases of gonorrhea. Some of the cocci were free; most of them, however, were contained within the leukocytes. They decolorized by Gram's method. In some parts of the pus there was apparently a pure culture of the gonococcus, in others bacilli and cocci could be found.

The patient at that time and before had no itching or

pain about the anus or rectum, no tenesmus or other unusual sensation, except the slight uneasiness, probably a feeling of fulness, as the tumefaction of the walls of the gut was quite marked. There were no constitutional symptoms except at times a very slight degree of fever.

It seems as if the infection in this case must have taken place by means of the suppositories referred to as having been employed in treatment. These were introduced at night, after dressing the glans. No antiseptics were used for the urethritis. The fingers were not introduced within the anus, except in inserting the suppositories. The case of Rollet, in which a patient with urethritis, who provoked stools by putting his fingers in the rectum, and who eventually inoculated the anus, is often quoted. (*Dict. Encyc.*, Art. "Anus: Maux Syphilitiques," p. 494.)

There seems to be no reason for doubting the patient's statements. Though extremely hypochondriacal, the man gave no history or sign of sexual perversion. There was no evidence of pederasty. He slept alone. The history of the urethral gonorrhea, it is true, is rather suspicious, though not entirely improbable. But these are not essential matters. The very obscurity of the mode of origin, in connection with the insignificant symptoms, indicates how easy it would be to overlook such a condition.

Although some writers maintain that gonorrhea of the rectum can only arise from sodomic practices, the case of Rollet constitutes an exception, and the same writer, as well as others, holds that, in women with gonorrhea, infection of the anus takes place from the spread of the discharges. A case is reported in the *Maryland Med. Journal*, June 1, 1882, in which rectal gonorrhea was observed in a woman without a history of pederasty.

It has been supposed (A. Bonnière, "Recherches nouvelles sur la Blennorrhagie," *Arch. gén. de Méd.*, April, 1874, p. 405) that the rectal mucous membrane is not inoculable with the gonorrheal virus. This view must be abandoned in view of the histologic examinations of Frisch. In my own case there could be little doubt that the specific inflammation involved all the parts visibly affected, but I could not obtain tissue in order to confirm the results of the observer just named.

The patient remained under observation several weeks. He used suppositories of iodoform, two grains each; later, small injections of creolin, 1 per cent. The redness and swelling subsided considerably. The amount of pus diminished, though there was always a good deal of it. The pus never appeared again, as on the first occasion, giving rise to a call to stool. The number of gonococci diminished slightly, the cells being less thickly filled with them.

The pus was always the same in its microscopic appearances and rather peculiar. It was pale-yellow and appeared in small lenticular bits floating in a clear, watery mucus. Numbers of these bits made up the larger masses always to be found within the rectum, between the folds.

There were never marked local symptoms, except after using the creolin, which caused burning. Later, defecation was sometimes painful. There was never excoriation or redness outside the anus, as described by the older writers.

The urethritis in this case, though not severe, was very intractable. It was not affected by zinc sulphocarbolate, and yielded very slowly and imperfectly to silver nitrate.

The chronic nature of the rectal inflammation, with the considerable swelling of the submucous tissues, led to the thought of the development of stricture. Frisch, in reporting his own case, raised the question whether many so-called luetic strictures of the rectum were not really gonorrheal, and, in the light of the case just reported, the question seems an important one. In this connection the cases reported from Baltimore (MEDICAL NEWS, August 14, 1886, p. 180) acquire a new interest. It may be possible to learn something of their later histories.

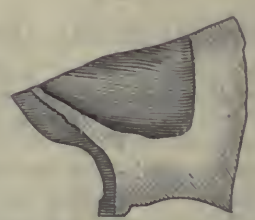
In my own case, as the patient could not be made to consider his rectal disease as more important than the imaginary ailment for which he presented himself, the later stages of the condition could not be followed.

A FOREIGN BODY IMPACTED IN THE LARYNX SEVENTEEN MONTHS; REMOVAL BY LARYNGO-TRACHEOTOMY; RECOVERY.

BY J. F. KLINEDINST, M.D.,
EYE, EAR, AND THROAT SURGEON TO YORK HOSPITAL AND DISPENSARY, YORK, PA.

L. H., thirty-nine years old, a farmer, on April 28, 1891, while cutting down a tree, was struck upon the back of the neck by a heavy falling limb and thrown to the ground. Consciousness was lost. The man was immediately picked up by his companions, carried to the house, and a physician summoned. After a half-hour consciousness returned, but there was inability to speak and complaint of a sense of suffocation. Examination of the mouth disclosed that an upper set of three artificial teeth, which the man had been wearing, was missing, and it was at once surmised he had swallowed it. His companions repaired to the place where he had fallen and there found the three artificial teeth, attached to a small piece of the broken plate, and, also, a part of the plate about the size of a pea. The greater part of the rubber plate was, however, missing.

FIG. 1.



For nine days the man suffered inexpressible agony, gasping for breath, and spent most of this time sitting in a chair, not being able to lie down. At the expiration of this time, during a violent attack of coughing, with threatening suffocation, he expelled the larger part of the missing plate of rubber. (Fig. 1.) He now was greatly relieved, could breathe with more ease, and was able to sleep at night in the recumbent posture. Sleep was, however, not as sound as before the accident, for

he was awakened at times by violent attacks of coughing and a sense of suffocation, which would gradually subside, when he could resume sleep. His voice, however, had not yet returned. What had become of the remaining part of the rubber plate was a mystery. The patient was not conscious of the presence of a foreign body in his larynx. The loss of voice and the other symptoms of laryngeal irritation were attributed to the irritation resulting from the nine days' sojourn of the piece of plate and its subsequent expulsion. From this time on the man's health began to fail and his voice did not entirely return until several months later, and even then it remained husky up to the time of operation. Following the accident there had been a constant cough.

In the fall of 1891, about six months after the accident, he had repeated chills and some fever; and soon he began to expectorate muco-purulent matter and to have night sweats; his breath also became offensive. In April, 1892, he expectorated some blood. These symptoms all seemed confirmatory of a diagnosis of tuberculosis, in which it was believed the larynx participated. Some time later the man was presented by his physician to the Medico-Pathological Society of York County, when I first saw him. He was emaciated; his complexion was sallow; his expression anxious and distressed. His breath was exceedingly offensive and of a grangrenous odor. A constant laryngeal cough was present, with muco-purulent expectoration. The temperature was slightly elevated and the pulse-beat accelerated. A physical examination of the chest revealed only bronchial râles; no cavities or consolidation in any part of either lung. The voice was husky and weak. A presumptive diagnosis of a foreign body in the larynx was made. On laryngoscopic examination the missing piece of plate was seen lying in the larynx

Fig 2.

Fig 3.

in an antero-posterior direction, with its serrated edge upward and about one-eighth of an inch below the vocal bands. (Fig. 2.) An operation for its removal was advised and was performed in the presence of a number of physicians at the York Hospital, October 3, 1892.

About half an hour before the operation the patient was given a hypodermatic injection of morphine and atropine, and was then anesthetized with chloroform. The skin over the larynx and trachea having been rendered aseptic, an incision was made through skin and fascia, from about the middle of the thyroid cartilage downward about two inches and a half. After all hemorrhage was stopped an incision was made in the larynx through the crico-thyroid membrane, cricoid cartilage, and downward through the first two rings of the trachea. The edges of the wound being retracted, an angular nasal polypus-forceps was introduced upward into the larynx and grasped the piece of plate, which, after a strong pull, could not be dislodged. The forceps was withdrawn and again introduced upward, but more nearly perpendicularly, and again grasped the piece of plate; by giving the forceps a slight turn to the right, I succeeded in dislodging and removing the foreign body. (Fig. 3.) A rubber canula was then introduced into the inferior portion of the opening in the trachea. The crico-thyroid membrane, cricoid cartilage, and trachea, above the canula, were united with carbolized catgut sutures, while the skin and fascia were united with silk sutures. The usual antiseptic dressings were applied around the canula. Over the mouth of the canula was kept a thin layer of moistened sublimate gauze through which the patient could breathe.

During the time that the canula was in the trachea, the temperature of the room was kept at from 75° to 80°, and the atmosphere was charged with moisture from a kettle of boiling water. The object of having the temperature of the room so high and its atmosphere charged with moisture, was for the purpose of approximating the condition of the inspired air to that in which it would be if inspired through the nostrils. The patient's temperature, seven hours after the operation, was 100.2°, falling to 100° on the following day, and continuing thus for four days, when it began to gradually fall until the eighth day, when it reached 99.2°, where it remained until the patient was discharged.

There was not much discharge from the canula or wound, except on the day following the operation, when there was discharged from the canula some muco-pus, evidently from the situation in which the foreign body had been impacted. On the third day the canula was removed, and the opening in the trachea closed in three days by healthy granulations. The dressings were changed daily, and on the fourteenth day the patient was discharged from the hospital, with the upper portion of the wound entirely healed and the lower portion covered with a cicatrix. Upon his discharge the patient was greatly improved in appearance and color. Cough had ceased; the expectoration was changed in character; the offensiveness of the breath had disappeared; and the voice had become more clear, although still husky and weak. Four weeks after his discharge from the hospital the improvement was still more marked. The man was much stouter and had gained nineteen pounds in weight.

There are several points of interest in this case. The first that attracts attention is the remarkable tolerance, by the larynx, of a foreign body so large as the one removed. Again, the extraction of such a foreign body by means of the laryngeal forceps would have been impossible, because of its situation and the fact that it had become imbedded. The symptoms presented a striking resemblance to those of laryngeal tuberculosis, but a careful and thorough examination was sufficient to disprove such a diagnosis. Finally, the case demonstrates the point that when a foreign body is impacted below the rima glottidis the only safe and proper method of extraction is by tracheotomy or, preferably, laryngo-tracheotomy, which does not entail any serious injury upon the vocal apparatus.

MEDICAL PROGRESS.

A Complicated Labor.—BEUGNIES (*Journal de Méd. de Paris*, vol. v, ser. 2. No. 8, p. 95) has reported the case of a primipara, twenty-two years old, who had been in labor for forty-eight hours, in consequence of dystocia dependent upon pelvic narrowing. The cord was prolapsed and the child was dead. The head was at the superior strait, and could not be dislodged by means of the forceps, even after peforation of the vault of the cranium. With the forceps still applied to the fetal head, symphysiotomy was performed and the child extracted. Incisions were made on either side of the vulvar outlet to facilitate the delivery of the head. The principles of antisepsis had been rigorously observed, although the surroundings had been most unfavorable. There was considerable hemorrhage. The symphysis was reunited by means of a strong silk suture. The patient did well for a day or two; then the temperature began to rise, the respiration became accelerated, diarrhea set in, and the wound and the vagina presented manifestations of gangrenous lymphangitis, to which pneumonia of the left base became superadded, and the woman succumbed on the fifteenth day after the operation.

The Transmission of Cholera through the Intermediation of Flies.—SAWTSCHENKO (*Centralbl. f. Bakteriologie u. Parasitenk.*, xii, 25, p. 893), has found that virulent cholera-bacilli appear for at least four days in the intestinal canal and dejections of flies that have been fed cultures of cholera-bacilli or the intestinal contents of cholera-patients or cholera-victims. There is evidence not only that the bacilli pass through, but also that they undergo multiplication in the intestinal tract of the flies. The greater the interval between the time of infection and the examination of the excrement, the smaller the number of saprophytic organisms found and the larger that of the cholera-bacilli. Control-experiments with the excrement of flies that were not exposed to infection gave negative results. It would thus seem demonstrated that flies may act not only as the carriers, but also as the hosts of the cholera-infection. This fact will, perhaps, explain the occurrence of epidemics during dry and hot weather, as well as a relative diminution in the number of cases after a heavy rainfall or decline in temperature.

A Delicate Test for the Presence of Albumin in Urine.—SPIEGLER (*Centralbl. f. klin. Medicin*, No. 3, 1893, p. 49) has modified the formula originally proposed by him for the detection of minute quantities of albumin in the urine (see THE NEWS, August 27, 1892, p. 246) by substituting glycerin for sugar, as the former is less readily reduced than the latter, and the resulting solution is the more permanently active. The modified formula, then, contains: Tartaric acid, 1 part; mercuric chlorid, 2 parts; glycerin, 20 parts; and distilled water, 50 parts. It is claimed that 1 part of albumin in 350,000 can be detected with this solution, when fresh; and 1 part in 250,000 when the solution is not fresh. The urine must, in every instance, be first treated with concentrated acetic acid, and, if turbid, be filtered to remove the mucin present. The test is not available if the urine contain iodin in any form, as this halogen will combine with the mercury in solution and give rise to the formation of a whitish or yellowish ring at the line of contact, which, however, is soluble in alcohol.

Post-marital Amblyopia consists in failure of vision of variable intensity consequent on sexual excess. The liability of certain persons to this form of amaurosis has long been recognized, and though probably of rare occurrence, it deserves to be made widely known on account of the prognostic importance of a correct etiological deduction. In the last number of the *Archives of Surgery* MR. JONATHAN HUTCHINSON relates three very typical examples of this affection, the most remarkable feature whereof is the readiness with which it is recovered from. In this respect post-marital amblyopia presents a striking resemblance to tobacco amblyopia, of which recovery and freedom from relapse are very definite features. It differs from the latter in being much more rapid in its development and in passing to a far higher degree of amblyopia. Though recovery is the rule, it must not be forgotten that in both series cases may and do occur in which the disease advances to complete and permanent blindness.—*Medical Press and Circular.*

Symphysiotomy.—REGNIER (*Centralblatt f. Gynäkol.*, xvii, 6, p. 108) has reported the case of a deutipara, twenty-nine years old, with a flat rachitic pelvis, of which the true conjugate measured 2.88 inches. The first pregnancy terminated in the delivery of a living child at term by means of the Cesarean operation. When, at the termination of the second pregnancy, labor set in, symphysiotomy was determined upon and carried out, a separation of 2.1 inches being secured. It was deemed best to suture the symphysis by means of silver wire. The child was a male. The result was successful, both for parent and child.

A Hitherto Undescribed Symptom of Hereditary Syphilis.—CARINI (*Internationale klinische Rundschau*, vii, 1, 3 4) reports nine cases of hereditary syphilis, in which the earliest symptom of the specific infection observed was singultus. This resisted the usual treatment for the affection, but speedily yielded to the administration of potassium iodid to the nursing parent and of mercuric chlorid to the infant. The manifestation is thought to depend upon the calling into activity of a neuropathic tendency as a result of the toxicity of the blood.

A Delicate Test for the Presence of Biliary Coloring-matter in the Urine consists, according to ROSIN (*Berliner klin. Wochenschr.*, No. 5, 1893, p. 106), in overlaying a small quantity of urine with a solution of one part of tincture of iodin in ten parts of alcohol. If biliary coloring-matter be present, a grass-green ring forms at the line of contact of the two fluids; in the absence of the biliary coloring-matter urine is simply decolorized at the line of contact.

The Vitality of Comma-bacilli.—As the result of a biologic study UFFELMANN (*Berliner klin. Wochenschr.*, 1893, xxx, 7, p. 158) found that comma-bacilli possess considerable resistance to cold. They survive exposure to a temperature of 12.6° F.; the result depends upon the intensity of the cold and the duration of the exposure. A decided difference was observed in the behavior of recent and of old cultures.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 25, 1893.

A NEW STUDY OF THE ACTION OF CHLOROFORM.

IN some recent numbers of the *British Medical Journal*[1] there is a tedious and not very lucid account of some physiologic experiments with chloroform. It is believed by DRS. GASKELL and SHORE, the authors of these studies, that their results support, if they do not prove, the following proposition: "*That the fall of blood-pressure caused by the administration of chloroform is due primarily to a weakening of the heart's action and not to paralysis of the vasomotor center.*" There is truth, undoubtedly, in this proposition, as we have had occasion to point out in a recent issue of THE NEWS. Nay, we think that proof much neater and clearer than any afforded by the papers before us exists in the *Memoirs of the French Academy of Medicine* and elsewhere in the writings of the French physiologists. But DRS. GASKELL and SHORE, our present authors, have a liking for a method the very reverse of neatness and clearness, for a method plentifully bespattered with blood and brains, for work in which lucidity is depised, in which the clear element is separated from the dense by a line "palpable to feeling as to sight."

In a prolix account we are introduced to some new and ingenious experiments. They are original with our authors, as we are told in a solemn letter,[1] and are contrived on the following plan. We quote from the *British Medical Journal*, January 28, 1893, p. 165:

"In order that chloroform, when inhaled in the ordinary way, could be carried to the brain only, or to the heart only, the circulation through the brain was separated from the general circulation, and a supply of blood obtained from another animal. . . . In general the method adopted was to connect the cerebral ends of one or both carotids of the animal whose cerebral and general circulatory systems were to be separated, and this animal we will speak of as the *fed*, and the cardiac ends of one or both carotids, which we will call the *feeder*. . . . The remaining brain arteries of the fed were ligatured. One external jugular vein of the fed animal was similarly cross-connected to the cardiac end of one external jugular of the feeder, and the other external and the two internal jugulars of the fed animal were ligatured. . . . The larger animal was, when possible, always selected for the feeder. In most cases the external carotids of the fed animal were ligatured, so that the internal carotids received all the blood derived by cross-connection with the common carotids of the feeder. In all cases an adequate supply of blood was left to the brain of the feeder, for in no case were its vertebral arteries interfered with. . . . The blood-pressure in the general circulatory systems of both animals was registered from the femoral arteries.

In the feeder the blood-pressure was generally low; in the fed, on the contrary, the blood-pressure was generally high, for in preparing this animal for the cross-circulation—

"the ascending cervical artery on the right side was ligatured, and the two carotids, which had been connected to the left carotid of the feeder, were still clamped. The left vertebral and the left subclavian were also tied, the ligature of the latter vessel, which was even placed proximal to the origin of the vertebral, being to prevent any possibility of blood passing by the ascending cervical arteries from reaching, by anastomoses, the upper part of the vertebral. Thus the right vertebral was the only vessel left for the supply of blood to the brain."

We are assured that this terrific process of cutting and clamping resulted in no evil effects, except in one case:

"where the last brain artery was, by mistake, tied before the clamps on the connected vessels were removed. The 'fall of pressure in the feeder does not always occur.' . . . The rise of blood-pressure in the fed animal reaches it maximum rather quickly, and remains fairly constant."

Lastly, we come to the following laughable statement:

"Eight cross-circulation experiments were made, three

[1] A Report on the Physiological Action of Chloroform, with a Criticism of the Second Hyderabad Chloroform Commission, by W. H. Gaskell, M.D., F.R.S., and L. E. Shore, M.D. British Medical Journal, January 21, 28, and February 4, 1893.

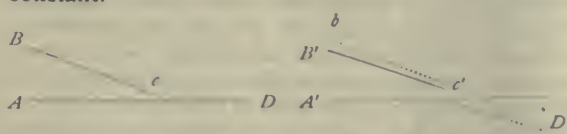
[1] Lancet, February 18, 1893, p. 386.

with two dogs, three with two rabbits, and two where the attempt was made to supply the brain of a rabbit with blood from a dog. This last procedure was unsuccessful, as the rabbit in both cases died very soon after the cross-circulation was established."

As soon as the cross-circulation, which seems to have flowed on quietly, was established, chloroform was administered to the feeder by means of a tube fixed in the trachea. In this animal the blood-pressure fell, and anesthesia supervened in 1 min. 20 sec. In the fed the blood-pressure arose, and it was observed that once, at least, the conjunctival reflex in this animal was abolished.

Now, it appears to us that results arrived at in this way are not very satisfactory. Many times in reading the present account of them we have been tempted to exclaim: "*Anceps hic et lubricus locus est.*" The authors of these curious investigations seem to be unacquainted with the limits of the experimental procedure. To them a healthy organism and a maimed organism subjected to the same stimulus will manifest identical phenomena. We think this by no means clear. As a matter of fact, such a principle is true only of physiologic experiments of the simplest kind—of experiments in which the sequence of cause and effect is obviously and necessarily plain. But in expeerimnts like those of DRS. GASKELL and SHORE, there is an element of error present, which may be shown best by an illustration from physics.

A and *B* are two known forces acting together at the point *c*, with a resultant *D*. This resultant is constant.



A' and *B'* are likewise two known forces acting together at the point *c'*, but simultaneously acting with *B'* is the unknown force *b*. The resultant cannot be the same as in the first case. The first case is that in which chloroform, represented in our illustration as the force *B*, is alone acting on the brain of a healthy animal, which we have chosen to represent as the force *A*. In the second case the conditions are the same, *A*, *B*, and *A'*, *B'*, being identical, except that there is an unknown modifying force *b*, at work with *B'*. This modifying force is composed of all those alterative influences active in an organism in process of dissolution.

But let us proceed to make this clear in another way. In any physiologic experiment, when it becomes necessary to act with an animal artificially maimed, or, to use an apt and significant phrase, with the unity of its structure and organic mechanism impaired, there is always an element of error introduced in this way, which must be reckoned with. In experiments judiciously planned and executed this element of error is so plainly and so easily calculable that no one is ever perplexed by it. Such experiments are extremely simple, and achieve great results by simple unvitiated means. They are simple, we say, because they are of such a nature and conception that there can be but one possible explanation of a single phenomenon, or order of phenomena, which are the subjects of investigation. Simplicity of conception, indeed, is the great point in any physiologic experiment, which must needs be inexact in its nature, and in its results difficult of proof. Hence, the great and signal advances in this science are made by experiments in which the sequence of cause and effect is plain, such as SIR CHARLES BELL'S or MAGENDIE'S to demonstrate the functions of the roots of the cord.

But in the experiments which form the subject of our paper the element of error is present, as might be expected, and, unfortunately for the results, cannot be stated in exact terms, being obviously indefinable and incalculable.

Again, in these experiments there is another fallacious element, a multiplicity of possible explanations of a single phenomenon, or order of phenomena; not one explanation capable of proof, but three or four, perhaps mutually exclusive. For, when, to take a pregnant instance, the question is asked: Why may not the rise of blood-pressure, which our authors have noted, be due, for one thing, to a rise of intra-cranial pressure? we are met by the following extraordinary assertions: "These experiments conclusively show that chloroform taken up by the blood in the lungs in the ordinary way and carried to the brain, only leads to a rise and not to a fall of blood-pressure." Observe that in this sentence the fed and the feeder are classed as one an mal. The words: "chloroform taken up by the blood in the lungs in the ordinary way," refer to what takes place in the feeder, while the words: "carried to the brain only," refer to what takes place in the fed.

"This rise can only be due to a *direct* or *indirect* action on the vasomotor center. It cannot be due to increased intra-cranial pressure, which might be caused by more blood coming from the feeder, because it takes

place at a time when the *blood-pressure* of that animal is *tending to fall.* [Italics ours.] Again, it cannot be considered as merely dependent on a diminished supply of blood to the brain, a relative anemia, due to the *fall of the blood-pressure of the feeder*, because the *rise of pressure of the fed* is *usually* established before the *fall* in the *feeder* takes place. Again, the latter [*sic*] is, except late in the administration of the chloroform, only small in extent; while, from observations we have made on the *effect of ligature of the brain arteries successively*, it appears that a large *diminution* of the *blood-supply* of the brain needs to be made to lead to a marked and lasting rise of pressure."

Could there be found in the whole range of medical literature a more confused, absurd, and contradictory passage than this? It proves, if it proves anything at all, that chloroform causes both a rise and a fall of blood-pressure; and such, indeed, is the opinion of our authors:

"These cross-circulative experiments confirm absolutely the previous experiments in which chloroform was injected directly into the circulation. In both cases the blood containing chloroform excites the *vasomotor center and raises the blood-pressure when it reaches the medulla oblongata*, while it depresses the *heart's action and lowers the blood-pressure when it reaches the heart.*" [Italics ours.]

In these sentences, as in the others that we have quoted, the two animals of the experiment, the fed and the feeder, are classed together as one animal, as an individual in fact. The confusion here is very obvious. The excitation in the vasomotor center takes place in the fed; the action on the heart, and consequent fall of blood-pressure, in the feeder.

But even this is not accurate speaking. The excitation of the vasomotor centers, if it take place at all, must take place in both animals, but in the one animal—the fed—there is the excitation of the vasomotor center, and nothing else, and in the other animal—the feeder—there is, besides the vasomotor excitation, the action of chloroform on the heart and circulation. Can these two actions be conceived of as not influencing each other? We think not. To do so is to ignore well-known facts.[1] Besides this, the conditions of the two animals of the experiment are wholly different. We have already noted some of these differences, and there are others. There is the difference in the vascular tension; there is, also, the difference in the size and structure of the blood-corpuscles, for dogs and rabbits were both used. The effect of dog's blood on a rabbit's brain is a case so curious that we shall forbear to discuss it.

[1] See the investigations of M. Francois-Franck.

And can we then, even in fact, class the two animals of the experiment as one, and accept the result? Evidently not. The proof of this, and indeed the best proof of the unsoundness of this method of investigation is that by using the same means, the same procedure, the same organisms and stimuli, we may obtain precisely opposite results, as SURGEON LAWRIE has done.[1]

And what bearing can the results of investigations so confused and incoherent in character have on the great question of the action of chloroform on the human heart? The word incoherent, indeed, is a just and truly accurate qualification by which to describe a process of reasoning that applies such results in an analysis of the effect of chloroform on man. But, not even if these results were accurate could they have any practical bearing. To use a legal phrase, they are facts not relevant to the issue, which is the action of chloroform on man; nor are facts relevant to each other.[2] For even if we look at the bare results of these cross-circulation experiments the relation of cause and effect is not very clear. And chloroform never could, under any possibility, be administered to man as DRS. GASKELL and SHORE have administered it in their experiments. And until they succeed in doing this we may safely deny the validity of their method and results.

EDITORIAL COMMENTS.

Achillodynia.—SCHÜLLER (*Wiener medicin. Presse*, xxxiv, 7, p. 241) expresses the opinion that the symptoms of achillodynia (see THE MEDICAL NEWS, Feb. 18, 1893, p. 187) are dependent upon inflammation of a small synovial sac situated between the tendo Achillis and the tubercle of the os calcis. Gonorrhea was present in most of the cases under his observation. A tendency to flat-foot manifested itself after the disease had existed for some time, in consequence of the peculiarity of the gait adopted. The best therapeutic results were obtained from direct injections of a ten per cent. suspension of iodoform in glycerin, with an antiseptic dressing, followed by absolute rest for a week. In recent cases rest, with inunctions of mercurial ointment, sufficed. In obstinate cases incision, with evacuation of the contents of the synovial sac, was practised. If gonorrhea be present it must be relieved.

ROSENTHAL (*Wiener medicin. Presse*, xxxi, 10, p. 366) repudiates the views of Schüller and suggests that in some cases the symptoms of achillodynia may be dependent upon the presence of a neuroma between the tendon and the subjacent structures. He reports an illustrative case, in which, however, the symptoms were unilateral.

[1] THE MEDICAL NEWS, January 14, 1893, p. 53.

[2] Sir James Stephen: "A Digest of the Law of Evidence," Introduction, p. xii.

The painful affection of the feet described by MORTON (THE MEDICAL NEWS, June 20, 1891, p. 704; Oct. 8, 1892, p. 406), and the pododynia of Gross (*System of Surgery*) are different, though, perhaps, allied disorders.

MILLS (*Journal of Mental and Nervous Diseases*, April, 1888, p. 6) has briefly referred to a case which appears to belong in the category of achillodynia.

Temporarily Overridden.—The committee of the New York Academy of Medicine, which went to Albany to advocate a sensible, honest, and scientific plan of dealing with the Croton-water supply, has been contemptuously disregarded by the legislative rulers of this ring-ridden city and State. The committee proposed a commission of five scientific experts, who should be fitted by knowledge, experience, and public interest to deal with the problem in such a way as to prevent the pollution of the water-supply, and thereby a possible appalling calamity. The committee vainly urged that "The history of every cholera-epidemic has been the same, and no sane person doubts but that with an unguarded water supply for the city of New York, and a few cases of cholera among, for example, the Italian laborers employed on railroads and other works in Westchester, Dutchess, and Putnam Counties, it will be not alone twenty or fifty thousand inhabitants of this city who will perish, but we shall have established here in the United States an uncontrollable and inexhaustible reservoir of disease whence by every known line of travel the epidemic will spread to the furthest confines of the country."

The Senate thereupon passed the Ring's bill, and Tammany laughs at the defeat of every consideration of decency and public rights. Such displays are plainly the beginning of the end. The community will hardly endure much gambling with its health and life.

The Modern St. Peters.—The physicians, the homeopaths, and the eclectics of Connecticut have united to try and get some kind of a law passed that shall prohibit the State from becoming the Scamps' Asylum for all of the medical quacks and frauds driven out of other States. These, of course, made quite a "respectable" showing at the hearing of the measure. One of the arguments used was drawn from the Bible story of St. Peter and the lame man in the Temple. "If," said this wonderful advocate, "there had been a medical practice bill then, some one of the regulars would have said, 'Peter, have you a certificate from the health board of Judea?' 'No.' 'Peter, have you passed an examination in anatomy, physiology, medical chemistry, obstetrics, hygiene, surgery, pathology, diagnosis, and therapeutics, including practice and materia medica?' 'No.' 'Then we'll fine you $100 for treating this man without a certificate, and if we catch you doing it again we'll fine you $200 and give you six months in the Jerusalem jail.'"

The comparison of the modern medical mountebank with St. Peter might more truthfully, if not more modestly, have been limited to the fact that whereas Peter is reported to have lied three times, his would-be-imitator has never been known to tell the truth.

The Central Hospital of Philadelphia, just established at the corner of Broad and Race Streets, has instituted an innovation in its administration that is worthy of all praise and imitation. This consists in holding evening clinic-services from 5.30 to 8 o'clock, for out-patients. It is noteworthy that in all the popular zeal for charity and medical help of the poor, it has escaped attention that for a working man or woman to quit work to attend the dispensary in the daytime, often really puts him or her to serious inconvenience and to a greater expense in lost time than would result from the call at the physician's private office. A large proportion of dispensary patients have such slight ailments, or they consider them so slight, that rather than lose time from work, they neglect to seek medical advice until the disease has become serious. Taken in their incipiency many affections are aborted. The evening service thus becomes a true charity, and the remarkable success of the Central Hospital clinics, even in these first weeks of the work, is proof that the public perceives the motive of true philanthropy and the skill of the physicians—a most excellently chosen corps—in charge of the clinics.

Infanticide in Private Lying-in Houses.—Coroner Ashbridge, of Philadelphia, says that infanticide in the city is rapidly increasing. The increase in public cases of exposed children, etc., is manifest, but he plainly says that the concealed cases are still more rapidly growing in frequency. "Most infanticides are traceable to the private, unlicensed, and practically irresponsible lying-in houses with which this city swarms." He urges that all these houses should be put under legal surveillance, and that, furthermore, a public lying-in hospital be established. This is one of the most terrible problems that civilization has to face. It is clear that with the assumption by the public of the care of illegitimate children, the number of the illegitimate will tremendously increase; at the best it is a doubtful remedy suggested by Mr. Ashbridge. Whether the misery of infanticide is greater than that attendant upon a large number of illegitimate births, with the lessening of the sanctity of the marriage tie, is a question demanding great care in the answering.

Municipal Cleanliness.—By a largely increased mortality New York is learning anew the punishment of filthiness. Although the statistic lessons may not be as clear and striking elsewhere, the law must hold good that cleanliness is not only a matter of esthetics, but also a matter of life and death. Chicago, with her 3400 or more deaths within two years from typhoid fever alone, preaches the same eloquent lesson as to the relative value of cleanliness and of godliness. It is time, and past the time, that we set about a vigorous municipal house-cleaning. "It is an ill bird that fouls its own nest." It is almost incredible that with all our civilization we have not practically solved the simple questions of the removal and disposal of our own filth, but that great cities make sewers of their rivers and drink the diluted and diseased excreta.

Cholera and Water-supply.—The population of Hamburg and of its neighboring town, Altona, is about 750,000. Both cities make the river Elbe their common sewer. The water-supply of both is drawn from the contaminated river, that of Altona being more deeply and certainly

polluted than that of Hamburg. In Hamburg, last year, there were about 18,000 cases of cholera, with 7611 deaths reported, but Altona escaped with 562 cases and 328 deaths. It is believed that the escape of Altona is due to the fact that the more filthy water was comparatively freed from disease-germs by filtration through sand beds before it enters the city pipes. The less noxious water of the Hamburgers was not sand-filtered. The lesson is so clear that extensive filtration-works are being erected at the Hamburg intake.

Precocity Extraordinary.—Dr. Hopkins, of Thomasville, Ga., reports the case of a child, four years and three months of age, who is four feet and three inches high, weighs ninety pounds, with corresponding development of all the bodily organs. Attention is called to the boy of Salamis described by Pliny, who, within his life of seven years, was infant, adult, father, old man, and corpse. When one reflects upon such facts, one is appalled by our physiologic ignorance of the fundamental conditions and causes of our being. The mysteries of heredity and of corporeal development are so utterly impenetrable that the glib conceit of some philosophers, who doubt of nothing, is beyond contempt or pity.

The Prevention of Cholera in Minnesota.—A clean-cut law has been passed by the Legislature of Minnesota, providing against the importation, by transportation companies, of those infected with cholera or other infectious disease. The State's sanitary officers are empowered to detain, in quarantine, all vessels or railway conveyances in which such diseases may be found; to disinfect and fumigate at the expense of the railway or ship company; to fine and punish carelessness on the part of the companies, to isolate the passengers and their effects, and otherwise prevent the importation within the State of those affected with contagious disease.

Scandal-mongering Coroners.—A poor girl kills herself, and to feed the voracious appetite of the filth-loving public the coroner and his physicians divulge medically doubtful, and morally pernicious, details of the post-mortem table. What human right have physicians to increase the agony of the parents and the monomania of the salacious by such betrayals of trust? Members of the profession who thus besmirch us all should be told by their fellows what is thought of them.

Trichinæ in Hogs.—According to the investigations of the Laboratory of Natural History of the University of Iowa, the animals showing the largest number affected with trichinæ—about one in every ten—are those fed on slaughter-house offal. The next in order are the hogs kept in pens by private families. Those that roam large fields and that are fed on corn are almost entirely free.

Experiments with Cholera-Germs.—Two or three months ago Dr. Hasterlik, of Vienna, together with four others, for purposes of experiment swallowed doses of pure cultures of cholera-spirilli. In some, diarrhea and a slight rise of temperature followed, but all recovered without serious illness. The bacilli were found in the excreta in each case.

Education of the Deaf and Dumb in England.—There seems to be a hopeful outlook in England for education of the poor deaf and dumb, at the public expense. A bill will soon be introduced to this effect. The number of these unfortunates is increasing.

The Medical Profession of Cincinnati, O., has been aroused as to the duty of harmony and organization. An enthusiastic meeting, largely attended, has resolved to secure a permanent meeting-place, and funds therefor were subscribed.

SOCIETY PROCEEDINGS.

THE NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, March 7, 1893.

DR. M. ALLEN STARR, PRESIDENT, IN THE CHAIR.

DR. FREDERICK PETERSON presented a case of Clonic Spasm of the Muscles of Mastication. The patient was a woman, fifty-seven years old, who six years previously had her upper teeth removed and replaced by artificial ones. The first set did not fit well, and a new one was substituted. The spasm developed as a result of the manipulations about the mouth, and of the necessity for keeping the mouth open for long periods of time. When sitting quietly and not using the muscles of the jaw, there was a continuous clonic spasm of the masseters, temporals, and pterygoids. The jaw opens and shuts slightly, and moves from side to side. The chief difficulty, however, is encountered in attempts to speak; then the mouth opens widely and there is a subluxation of the jaw downward and forward. During the first six months the mouth would not close at all, excepting at night, when the spasm relaxed.

Dr. Peterson said that while tonic spasm of the masticatory muscles, or trismus, is quite a common symptom, the condition presented in this case is very rare. As regards treatment, atropine, hyoscine, conium, and electricity were used perseveringly, without any noteworthy effect. Latterly, duboisine sulphate, in doses of gr. $\frac{1}{200}$, three times daily, has afforded much relief by quieting the spasmodic movements almost wholly at times. In addition, the woman wears an apparatus that keeps the jaws in apposition, and allows her to talk between her teeth, without the uncomfortable tonic spasm of the depressors of the jaw, although the clonic movements of the masseters and pterygoids may keep on as before.

DR. WILLIAM M. LESZYNSKY stated that he had seen a case of clonic spasm of both platysmæ, following prolonged manipulation of the lower jaw by a dentist. The spasm lasted only three or four days. Slight spasm of the muscles of the jaw after dental operations is not uncommon.

DR. EDWARD D. FISHER presented a case of Rhythmical Spasm of the Extremities. The patient was a woman, forty-three years old. The attacks had taken place for about a year. The spasm is sometimes confined to one or both arms, or to the lower extremities, or the motion may involve all the limbs at the same time. The attacks come on spontaneously, and last about five minutes. A number may occur during the day, or the patient may remain free for a day or two. The muscles are becom-

ing hypertrophied and more rigid, and it is difficult to bend the elbow or the arm. The woman complains of fatigue. Various methods of treatment, including hypnotism, have been employed, but without apparent effect. It seems impossible for the woman to control the spasm. There is no analgesia. Hysteria was thought to be the basis of the attacks.

DR. J. E. CULVER read a paper on "Innervation and the Functions of the Sympathetic Nerves." He reviewed at length the distribution and functions of the sympathetic nervous system, and traced the relationship between its disturbed innervation and the interference with respiration, oxidation of the blood, and other physiologic processes.

DR. WILLIAM H. THOMSON read a paper on "Basedow's Disease." He stated that the progress of pathology often illustrates the disadvantage of the premature naming of diseases after some common or prominent symptoms, for further knowledge may show much wider relationships than were at first suspected; and in some cases these symptoms may be absent. Under such circumstances the symptomatic name may operate to prevent a correct diagnosis. The name exophthalmic goiter has had much influence in preventing the recognition of Graves's disease in many instances, and still more in confusing the views as to its pathology. The conception of some textural lesion in the nervous system to account for the exophthalmos and goiter has diverted investigation and speculation, in seeming forgetfulness of the fact that these symptoms are not essential to the affection, for they may exist in the absence or be absent in a case of Graves's disease. A safe rule to follow in the study of pathologic problems is to seek first for the most constant characteristics of a given affection rather than for the most obtrusive ones. Thus, the most uniform condition in Graves's disease is what may be correctly described as a state of marked agitation. In many instances this is for a long time a purely physical state, not involving the mind or the spirits, and yet the patient acts as if greatly alarmed about something. As a consequence, many writers consider fright a leading cause of the disease. We are thus at the outset diverted from the study of a characteristic condition to that of an occasional element in the clinical history of the affection.

Dr. Thomson then detailed the histories of eight consecutive cases of Graves's disease. In none was fright or other emotion an element of the clinical history. With two exceptions, all were unusually free from causes of mental strain or depression. Exophthalmos and goiter were absent in one case; exophthalmos alone was absent in five. Goiter was absent in one, while in another it was only slightly present late in the disease. Both exophthalmos and goiter were marked only in one case. In all the cases there was pronounced tachycardia and muscular tremor. Emaciation was marked in five and moderate in three; in four, imperfect inspiratory power was noticed.

The rapidity of heart-action and the muscular tremor are the first symptoms to develop and the last to disappear, and, together, they constitute the most invariable elements of the disease. Attention should, therefore, be particularly directed to them as the most closely related to its pathology, and the most important practically—as the earlier the disease is recognized, the better for the patient. A paralytic lesion, involving the common nucleus of the glosso-pharyngeal, vagus, and spinal accessory nerves, and extending to the neighboring vasomotor center in the medulla, would account for the whole group of symptoms that make up the picture of Graves's disease. Simple irritation of the lower branches of the glosso-pharyngeal and of the superior laryngeal nerves is sometimes accompanied by general muscular tremor. Such a bulbar lesion would also explain the tachycardia and the universal relaxation and throbbing of the systemic arteries. It would also explain the interference with the inspiratory expansion. Such a lesion would not, however, account for the exophthalmos or the goiter, and actually evidence is wanting of a constant textural lesion in the medulla, either of the centers mentioned or of other parts. No characteristic anatomic change has yet been discovered which can be causally associated with the genesis of Graves's disease, and the origin of the malady must be looked for elsewhere. In this connection clinical experience may furnish aid. Persistent diarrhea is a common symptom in Graves's disease. In the cases reported, astringents and other drugs had little effect in checking the diarrhea, while a change of diet at once brought about an improvement in all the symptoms.

Dr. Thomson stated that he mainly relies on the dietetic treatment of Graves's disease, and with such favorable results that he has little doubt that a specific disorder of intestinal (in distinction from gastric) digestion is the primary factor in the genesis of the affection. While a structural lesion in the medulla that would account for the phenomena of Graves's disease is almost inconceivable without involvement, sooner or later, of all the vital functions of that important part, particular functional derangements, produced by toxic agents of intestinal origin, are just what might be expected; for nothing is more characteristic than the narrowly selective operation of functional nervous poisons, which may go on for years, as in the case of opium, affecting certain functions, without producing either progressive changes in them or extension to other functions. One fact in Graves's disease which points much more distinctly to a digestive disorder than to a structural nervous lesion is that it occurs in women about ten times as often as in men. That the digestive apparatus in women is subject to special disorders is well known.

Dr. Thomson stated that he has not yet seen a severe case of Graves's disease in which diarrhea was not, sooner or later, a pronounced symptom. As regards the diet in these cases, the amount of meat taken should be restricted, and milk, in some acceptable form, should be substituted. Medicinally, intestinal antiseptic remedies are to be employed, together with the tincture of strophanthus as a vasomotor tonic.

DR. E. C. SEGUIN expressed the belief that while there are undoubtedly cases of Graves's disease in which one or two of the three prominent symptoms — exophthalmos, goiter, and tachycardia—are absent, the number of cases in which the principal symptoms are those relating to the circulation had been rather exaggerated. The cases in which the only gross symptoms are the rapid heart-action and the tremor are comparatively rare. On the other hand, there are cases which present these

symptoms, to which he would hesitate to give the name Graves's disease. Many cases of disease of the heart, with dilatation or tachycardia, are likely to be associated with muscular tremor and considerable nervousness. There are other symptoms to assist in arriving at a diagnosis of Graves's disease. One is the character of the pulse. The mere fact of the pulse being rapid is not in itself characteristic of Basedow's disease; it should possess a quality of tension and smallness which to the experienced finger is of value in making the diagnosis. Then, again, the temperature, taken in the axilla, is invariably raised from one-half to one degree F. As to the pathology of the disease, the theories as to the location of a lesion in the central nervous system or in the medulla are not satisfactory. As to locating the general cause of the disease in the intestinal tract, no positive conclusions can be drawn, for the reason that diarrhea is by no means a frequent symptom in Graves's disease. Furthermore, the diarrhea does not appear to be fermentative in character; it is, on the contrary, of a paralytic nature, the evacuations being large, liquid, and frequent. Dr. Seguin referred to the value of aconitine in treatment.

Dr. B. Sachs stated that he has found the "rest treatment" extremely beneficial, the heart's action becoming better and the goiter diminishing in size. In addition to rest, he puts the patient on a light diet, consisting principally of milk and eggs.

Dr. Mary Putnam Jacobi referred to three cases in which depressing emotions had preceded the development of exophthalmic goiter. In one of these, a very severe case, the patient was a woman, aged twenty-two years, whose marriage engagement was broken by the sudden death of her *fiancé*. She rapidly developed the three typical symptoms of Graves's disease, with intense anorexia and diarrhea. She remained in a state of great prostration for six months, and subsequently recovered after marrying somebody else. Following her second pregnancy her symptoms reappeared. She was at that time living almost entirely on champagne, which seemed to greatly intensify the symptoms. The diarrhea did not appear to add to her prostration. The patient was put on a meat-diet, and the pulse rapidly fell from 150 to 90 per minute, and she regained her strength. In another case, occurring in a woman forty-two years old, the symptoms appeared after prolonged family troubles. The third case was also in a woman, a domestic servant, who developed the symptoms after prolonged nursing of her mistress, to whom she was much attached.

Dr. Joseph Collins said that if a toxic origin were ascribed to exophthalmic goiter, the prognosis would be less unfavorable than it is. In some experiments he has found that complete extirpation of the thyroid gland is almost invariably followed by death. This would controvert the idea that the function of the gland is a metabolic rather than a secretive one.

Dr. A. D. Rockwell referred to the value of digitalis in cases in which there is a weakness of the myocardium; he has found the drug very serviceable, in combination with iron, zinc, and ergot. He also referred to the value of electricity; in order to do any good, the current must be sufficiently powerful. In reply to a question, Dr. Rockwell said that the diminished resistance to the electric current is probably owing to the perspiration and to the better conduction due to the rapid circulation.

The President expressed the belief that no explanation thus far given will cover all cases of exophthalmic goiter, and it is doubtful that a single explanation will be found for all cases of any functional nervous disease. In two cases of Graves's disease recently under observation, sudden fright was too immediate to be anything but causative. One of the patients, a woman, saw her baby fall from a second-story window. She was immediately seized with palpitation, and within two weeks developed exophthalmos and goiter. She presented an interesting symptom that has been referred to by Charcot, a sudden giving out of the limbs—astasia. After such a collapse she is perfectly able to rise and walk away. In another case, the symptoms developed suddenly in a patient after she had narrowly escaped being run over by a street-car.

Dr. Thomson, in closing the discussion, said that he did not mean to imply that fright and depressing emotions do not repeatedly furnish the occasion for the first development of the symptoms, but it is important to separate occasions from causes. The tremor of Graves's disease is characteristic; it is different from the tremor of any cardiac affection. It is not maintained that there is a lesion in the medulla to account for the symptoms; the absence of such a lesion gives support to the toxic theory. The relapsing nature of Graves's disease is opposed to the idea of a structural lesion.

Cases attended with a pulse of high tension are associated with albuminuria. In Graves's disease there is a dilatation of the arteries throughout the body, and dilated arteries and a pulse of high tension do not go together. The elevation of temperature is slight, such as may be present in any serious neurosis, but it bears no proportion to the rapidity of heart-action, and the affection may be essentially regarded as a non-febrile disease.

CORRESPONDENCE.

YELLOW-FEVER INOCULATION.

To the Editor of The Medical News,

Sir: The sharp practices engendered by the associations of Washington City have enabled a prominent member of the medical profession in this country to forestall and checkmate the legitimate outgrowth of the facts presented by Domingos Freire in regard to the results of yellow-fever inoculation in Brazil. But the old maxim of *magna est veritas et prevalebit* still holds its place in the developments of the efficacy of inoculation as a preventive of yellow fever.

The data presented in my article entitled "Facts *versus* Fiction Touching Yellow-fever Inoculation," which appeared in *The Journal of the American Medical Association* for March 22, 1890 (reprints being on hand) are fully corroborated by a report of the recent work of Domingos Freire in the city of Rio de Janeiro, where the good results of inoculation are clearly shown. The following is translated from the *Jornal de Brazil*, of Rio de Janeiro, January 28, 1893:

"Vaccination Against Yellow Fever.

"Dr. Domingos Freire writes us: 'The total number of inoculations for the prevention of yellow fever during

the epidemic of 1891-92 was one thousand, distributed as follows: 81 in Nitheroy; 28 in Barra Uansa; 38 in Rezende; 34 in Paralujba do Sul; 818 in Rio de Janeiro.

"'There were 377 foreigners and 623 natives. The foreigners were of the following nationalities: Portuguese, 220; Italians, 81; Spaniards, 30; French, 29; Austrian, 5; Argentine Republicans, 3; Eastern, 3; German, 1; Englishman, 1; Pole, 1; Russian, 1; Swede, 1; North American, 1.

"'Of the Brazilians inoculated the following provinces were represented by the number opposite the name:

"' Rio de Janeiro (city)	399
" " (state)	123
Minas Geraes	26
Parahyba do Norte	16
Rio Grande do Sul	14
San Paulo	15
Espiritu Santo	3
Pernambuco	4
Alagoas	3
Matto Grosso	2
Ceará	2
Pará	1
Paraná	1
Bahia	13

"'Nearly the total number were in the most probable condition to contract the disease. The great majority had been in Rio de Janeiro varying from a few days to four years. Then, in calculating the lowest period of receptivity, it is put down as five years' residence in the infected place as the minimum period for acclimatization. The individuals inoculated lived, for the most part, in the streets where the disease had become most widely developed.

"'The mortality among those inoculated was 0.8 per cent. (eight-tenths of 1 per cent.).—During the same epidemic there died about four thousand people who had not been inoculated. From 1883 to 1892 there have been 11,881 inoculations to prevent yellow fever, with a mortality of 0.5 per cent. (five-tenths of 1 per cent.).

"'The results of the inoculations show that this prophylactic means has a real efficacy.'

"Shortly we expect to publish in all their details the statistics for 1891–92."

I am, Sir, respectfully yours,

J. MCFADDEN GASTON, M.D.

ATLANTA, GA.

NEWS ITEMS.

Section on Hygiene, Climatology, and Demography of the Pan-American Medical Congress.—Persons proposing to present papers before this Section are requested to communicate with either of the undersigned *immediately*, that titles of subjects may be properly classified for the program of the proceedings of the Congress. The only limitation as to subject matter is that it shall have a sanitary, climatologic, or statistical bearing. Members of the Section on State Medicine of the American Medical Association, the American Public Health Association, the American Climatological Association, the American Academy of Medicine, and of State and Municipal Boards of Health are especially invited to contribute the results of their several experiences. The languages of the Congress being Spanish, Portuguese, French, and English, papers may be presented in either, to be translated in the others, for which reason their text should be in the hands of the Secretaries at the earliest possible date. Albert L. Gihon, M.D., President, 145 East 21st Street, New York City; Pedro José Salicrup, M.D., Secretary (Spanish), 129 East 17th Street, New York City; Peter H. Brice, M.D., Secretary (English), Toronto, Canada.

International Semmelweiss Memorial.—Subscriptions are solicited to the memorial in honor of SEMMELWEISS, to be erected in his native city, Budapest, in recognition of his services to antiseptic midwifery (*Die Aetiologie der Begriff und die Prophylaxis des Kindbettfiebers*, 1861). The American members of the committee having the project in charge are: Dr. H. R. Bigelow and Dr. Barton Cooke Hirst, of Philadelphia; Dr. John S. Billings and Dr. A. F. A. King, of Washington, D.C.; Dr. E. W. Cushing, Dr. C. M. Green, Dr. Henry O. Marcy, Dr. L. W. Richardson, Dr. A. D. Sinclair, and Dr. W. Storer, of Boston, Mass.; Dr. W. W. Jaggard, of Chicago; Dr. J. H. Kellogg, of Battle Creek, Mich.; Dr. W. W. Potter, of Buffalo; and Dr. A. J. C. Skene, of Brooklyn. Dr. J. Elischer, Petöfi-tér 1, Budapest, Hungary, is the Treasurer, to whom subscriptions are to be forwarded, or to any of the American members of the committee, or to the editorial office of THE MEDICAL NEWS.

Anatomical Section of the Pan American Congress.—The following physicians have been appointed members of the Advisory Council: Dr. F. Mall, University of Chicago, Chicago; Dr. Charles S. Dolley, 3707 Woodland Ave., Philadelphia; Dr. Edward K. Dunham, Carnegie Laboratory, New York; Dr. Elizabeth B. Bundy, Woman's Medical College, Philadelphia; Dr. Wm. M. Gray, Army Medical Museum, Washington; Dr. H. C. Tinkham, University of Vermont, Burlington, Vt.

The American Climatological Association will hold its tenth annual meeting in Philadelphia, May 25th, 26th, and 27th.

Members having papers to present are requested to communicate with the President, Dr. R. G. Curtin, 22 S. 18th Street, Philadelphia, or the Secretary, Dr. J. B. Walker, 1617 Green Street, Philadelphia, at as early a day as possible.

The Section on Dermatology and Syphilography of the Pan-American Medical Congress has been fully organized, with Dr. A. H. Ohmann-Dumesnil, of St. Louis, Mo., as Executive President, and Dr. William S. Gottheil, of New York, as English-speaking Secretary, and Dr. John Forrest, of Charleston, S. C., as Spanish-speaking Secretary.

New York Eye and Ear Infirmary Reports is the title of a volume of original articles by the members of the surgical staff of the New York Eye and Ear Infirmary, successive numbers of which will appear as the material shall be collected. Part I of Volume I contains 111 well-printed and well-illustrated pages.

Error.—The title of Dr. Tyson's paper, p. 307, THE NEWS, March 18, should have been "Two Cases of Cystin Calculus," instead of "Two Cases of Cystic Calculus."

ORIGINAL ARTICLES.

DIPHTHERIA—A CLINICAL STUDY.[1]

BY WILLIAM P. MUNN, M.D.,
OF DENVER, COL.,
ASSISTANT PROFESSOR OF GENITO-URINARY DISEASES AND CLINICAL SURGERY IN THE UNIVERSITY OF DENVER; GENITO-URINARY SURGEON TO THE ARAPAHOE COUNTY HOSPITAL; PHYSICIAN IN CHARGE OF QUARANTINE, AND ASSISTANT HEALTH-COMMISSIONER OF THE CITY OF DENVER.

(*Concluded from page 316.*)

TREATMENT.—The rational and successful treatment of a disease so varied in its manifestations and so various in its intensity as is diphtheria must not be entirely empirical, but must be based upon a knowledge of its pathology. The aim of treatment must be to combat those conditions or to abort those processes that result in death.

The modes of death from diphtheria may be classified with more or less exactness as follows:

A. *From systemic causes:*

1. Inanition
   - Non-assimilation
     - Inability to digest.
     - Inability to absorb.
   - Inability to partake
     - Paralysis of the muscles of deglutition.
     - Inflammation of the fauces.
     - Obstruction by membrane.
   - Neglect of feeding.
2. Septic conditions
   - High temperature. Rare.
   - Hemorrhage due to lack of vitality of capillary walls.
   - Coma.
   - Degeneration of the blood.
3. General paralysis. Very rare.

B. *From local causes:*

1. Stenosis of larynx
   - By membrane.
   - By foreign body, on account of paralysis of muscles of deglutition.
2. "Heart-failure"
   - Fatty degeneration of heart.
   - Degeneration or inflammation of cardiac ganglia.
   - Disintegration of blood..
   - Endocarditis.
   - Paralysis of heart, due to central lesions of nervous system.
3. Pneumonia
   - Ordinary.
   - Septic.
   - Membrane-extension.

The conditions here outlined are, in their various modified or aberrant manifestations, almost legion; they may exist separately or at once, and a somewhat elaborate scheme of treatment is necessary in order to combat them. No hard-and-fast line can be drawn as to medicaments or dosage, for they may need to be varied almost from hour to hour. Few diseases—indeed, I am almost prompted to say, no other disease—demands so much or so varied medication, and in no other kind of sickness have I seen medication do so much absolute and incontrovertible good.

There is, however, no *specific* medication for diphtheria. No one remedy can cure all cases or keep up an uninterupted successful record during several successive epidemics or years. Nevertheless, it can be said without fear of contradiction that the general principles of therapeutics, faithfully followed, even in desperate cases, are here, as almost nowhere else, productive of results that are gratifying to both physician and patient.

Inanition must be combated by systematic attention to the diet. Easily-digested and easily-absorbed materials are a necessity, and should be administered with regularity at short intervals. Peptonized milk is of great value; beef-juice, freshly expressed, may be given frequently in small doses; the white of an egg, well beaten, with pepsin added, is easily retained, and may be given either by mouth or by rectum; oatmeal or cracked wheat will often be very grateful to the patient, and may be given freely.

The treatment of the septic conditions must aim (1) to encourage excretion, and especially by such methods as will carry off the toxic products that have been thrown into or formed in the blood; (2) to increase the resisting power of the tissues and especially of the hematic elements; (3) to antagonize the vitality and development of microörganisms, and (4) to destroy or neutralize the chemical products of germ-life.

The remedies that have given me most satisfactory results in meeting the indications just named are calomel, tincture of iron chlorid, whiskey, and mercury bichlorid or biniodid.

The effect of calomel on the system made it years ago the one great remedy in medical practice. An unintelligent prejudice has, during the past generation, kept it from being employed frequently or efficiently; but we are again coming to appreciate the fact that "modification of the secretions and excretions" is an essential of successful medical treatment. Especially is this true of diphtheria, in the therapy of which disease calomel now holds a leading place.

Given in a dosage which seldom needs any limitation until its characteristic effect is produced, I have never seen calomel do harm. But, as the

[1] A paper read before the Denver and Arapahoe Medical Society, December 13, 1892.

dosage is for effect, it should be discontinued or decreased when that effect, as indicated by thin, green bowel-movements, has been produced. Sometimes a total of ten grains, given in doses of one grain every hour, will be sufficient to produce the result. At other times as much as 200 grains will be required.

In answering the question: "What does calomel do and how does it do it?" one must depend partly on facts and partly on theory. The general condition of the patient is improved, the color becomes better, the pulse steadier and firmer, the tendency to coma is less, the bowels and kidneys both act more freely. In the throat it is observed that the spread of the membrane is limited or, at least, the rapidity of its spread is decreased; thick membranes become thinner and thin ones fail to become thick; extension of the disease into adjacent organs, especially into the larynx seems to occur but rarely after the system has been mercurialized. That this accounts for the lessening necessity for operative interference, on account of laryngeal stenosis, in the practice of those who depend upon mercurial treatment of the disease, I am thoroughly convinced.

The manner in which calomel, as well as other mercurials, such as biniodid, bichlorid, or cyanid, produces these effects, I take to be this: *a*, by a cholagogue action, the blood is relieved of toxic materials and the abdominal circulation is stimulated, thus preventing blood-stasis in the spleen and liver, where the final biologic product of the diptheria-germ is largely formed, such formation being favored by stagnation of the current; *b*, the sympathetic nervous system is relieved of the depressing influence of generally-diffused venous and capillary pressure due to stagnation of blood-flow; *c*, the heart itself is no longer gorged with unhealthy venous blood, and acts more freely and with greater force; *d*, the toxic materials in the blood and lymph have their activity lessened or are partly rendered inert by the coagulating action of the mercurials; *e*, the germs themselves are destroyed and the toxic materials contained in them partially neutralized by coagulation; *f*, the changes thus brought about in the blood lessen the tendency to fibrin-exudation, and consequent membrane-formation at the local disease-focus.

It will be noted that this explanation covers not only the therapeutic action of the calomel, but the systemic effect of the mercurial salts. I am in the habit of giving the bichlorid or biniodid (there seems to be no choice between them) in solution or in tablet triturate form, in doses ranging from one-thirtieth to one-tenth of a grain, every one, two, or three hours. For a child of from two to five years old I begin with one-thirtieth of a grain every two hours, lessening the interval to one hour after a few doses, and doubling or trebling the dose at the end of the first or second day. The aim is to bring the system under the influence of the mercury as quickly as possible. When this is done the disease ceases to advance. Then I hold the medication at the dosage reached, or lessen the dose or increase the interval of administration as the case demands.

Of all the cases I have so treated only one was ptyalized. The patient was a female, aged twenty-six, to whom I had been giving one-sixteenth of a grain of mercury cyanid every hour for about one week. Membrane covered the fauces and the palate to within one-half inch of the teeth. In twelve hours the membrane disappeared synchronously with the unheralded appearance of severe ptyalism. There was no re-formation of membrane, but the woman's teeth were loose for many months, and for weeks she had to take a simple "slop-diet." There was no necrosis, and the recovery was ultimately perfect.

Alcoholic stimulants are also of primary importance, here even in greater degree than in other septic diseases. No other remedy is known that is as potent and diffusible. If any other of equal efficacy is ever discovered alcohol may be given up, but not until then.

In the therapy of diphtheria this remedy serves a triple purpose: *a*, It is a stimulant of unequalled efficacy; *b*, it is a readily oxidized food; *c*, it is an antiseptic agent, both locally and systemically. In severe forms of diphtheria it is almost impossible to give too much of it. The dosage must be large, frequent, persistent; never at greater intervals than two hours, often at as short intervals as fifteen minutes, and sometimes, when the patient's vitality is at a very low ebb, its administration may be practically constant, the alcoholic stimulant being, properly diluted, continually administered by means of a medicine dropper.

It is frequently observed that the failing circulation regains its vigor, the sinking patient rallies, as the diffusible stimulant begins to be absorbed; while, as the effect of the dose wears off, the circulation again fails and vitality again becomes enfeebled. The amount of stimulant necessary is of course dependent upon the individual case, but must always be in excess of that given in other diseases. Many patients under six years of age require the administration of an ounce of whiskey every hour for from two to six days, and to several I have given double that quantity, the patients recovering.

I have never yet observed the slightest harmful effect from the administration of alcoholics in diphtheria. In addition to its long-known stimulant properties, and its ready oxidation in the circulation, recent biochemic research has led to the conclusion that in diphtheria, at any rate, it has a

distinct antiseptic action. The albumoses formed in the diphtheric membrane are precipitated and their absorption is prevented by alcohol. The germs themselves are devitalized and the toxic substances already absorbed are probably rendered partly inert by the action of the alcohol, after its absorption into the circulation.

Iron, in the form of the tincture of the chlorid, has long been a favorite remedy in all diseases accompanied by degeneration of the hematic elements. In diphtheria its beneficent effects have also long been recognized. But it is ordinarily given in too small doses. We must not lose sight of the fact that we are not dealing with a simple anemic condition, but with one of profound toxemia, which is acute in onset, malignant in action, and overpowering in its effects.

Remembering these facts, and the additional one that probably not more than half of what is given is absorbed, let us give iron in large enough doses to do good. To children from two to five years old I give from five to ten drops at least every two hours, often every hour; to adults never less than ten minims each hour, and frequently twice or thrice that amount.

The treatment of weak heart is but little different from that demanded for the same condition accompanying other diseases. Digitalis, nux vomica, and strophanthus are the indicated remedies, and to them may be added convallaria, nitroglycerin, caffeine, camphor, and musk; alcoholics are already being administered.

In those cases in which weak heart is practically due to hemorrhage it would seem that transfusion might be resorted to. At least the one-fourth per cent. saline solution should be injected subcutaneously or into the bowels. Such a case was No. CIX of those reported. The boy was eight years old and had apparently completely recovered from a severe attack of diphtheria in which the membrane affected the fauces, palate, and both cavities of the nose. He began to sink suddenly; vomited continuously; his pulse became thready, and disappeared at the wrist fourteen hours before death; his lips were ashen, and he complained of an intolerable thirst, but could not retain water in the stomach. Digitalis and nux vomica were freely given. Hot saline enemas were given, but failed to relieve, and he died thirty hours after the first sign of collapse.

The autopsy revealed only congestion and slight suppuration in each kidney, and about two pints of serous fluid free in the peritoneal cavity. These conditions did not seem to be sufficient to account for death. I have felt that the patient might have recovered if the saline solution had been injected into his veins. Certainly in another case like it I shall resort to the measure.

Albumin in the urine does not seem to me to be an indication that is of any value as bearing upon treatment. In almost all cases the patient is already taking so much medicine for conditions of greater urgency that I do not see that any added medication will be justifiable. Nor does it seem, except in cases of suppuration like the one just cited, that albumin in the urine will have any bearing upon the final result of the sickness. During convalescence, should the albumin persist, I see no objection to the administration of some mild diuretic, like liquor ammonii acetatis. It seems probable, however, that the medication already described is good treatment for albuminuria, and as that is usually being given anyway, the detection or non-detection of albumin is a matter of indifference, so far as modification of treatment is concerned.

An additional remedy for systematic use is hydrogen dioxid. Patients whose lips are bluish-black, and with evidently impeded circulation, are benefited by its frequent free administration.

The ten-volume or fifteen-volume solutions of this drug, as found in the market, are innocuous even in excessive dosage, provided that they are pure. When there is an excesss of acid present, the drug will irritate or even denude the healthy mucous membrane. Of a pure specimen of the drug I give from one to four drams every hour, with the result in many cases of bringing a healthier pink color to lips and cheeks. The oxygen held in solution in the preparation is probably given up in the system, with the effect of promoting perfect oxidation and toning up the vitality of the red blood-corpuscles. Hydrogen dioxid should not be administered in metallic spoons, as they lessen or destroy its activity.

Local Medication.—Recognizing germs as the primary cause of diphtheria, local treatment is directed as follows:

1. Destroy the germs.
2. Neutralize their active products.
3. Limit membrane-formation and destroy what is already formed.

As has been stated, the remedies already recommended for internal administration have a local antiseptic and deterrent action, which must be exerted to some slight extent upon the local disease-focus as they pass over it. This slight action is, however, far from being efficient or sufficient. Energetic measures should be directed to the local trouble. Mechanical removal of the membrane has not given good results, as the violence necessary to accomplish it does harm to the underlying tissues, and the measure itself is ineffectual, new membrane appearing after a few hours. Destruction of the membrane and adjacent tissues by means of the actual cautery has been recently proposed. The proposition seems reasonable, but it is not feasible.

The proportion of patients whose families would permit such an operation at a time when it would prove effectual is very small indeed. Cauterants, such as silver nitrate, ferric alum, carbolic acid, nitric acid, chromic acid and similar compounds, both in strong and weak preparations, have been urgently advocated by some practitioners as invariably successful in removing and preventing reformation of the membrane. I have used silver nitrate and carbolic acid with but little success, and ferric alum with absolutely no success. The other agents proposed for this purpose seem so unsuitable that I have not used them.

Mixtures of iodin and carbolic acid of about 2 or 3 per cent. have been used with success by some practitioners, and I have ventured to rely upon them in a few mild cases, which fortunately recovered. The medication seemed to have no real effect upon the membrane.

The medicaments which have given me the most satisfactory results have been hydrogen dioxid (from three-volume to fifteen-volume solutions), corrosive sublimate, 1:2000 solution, carbolic acid, from 1 to 2 per cent. solution, and lime water. Trypsin and extract of pancreas I have used both in solution and in powder. While efficient, they are not to be compared to corrosive sublimate or to hydrogen dioxid sprayed with an atomizer. These two remedies I find of the greatest efficiency, and they may be used together without trouble. Except occasionally in adults, I have altogether stopped using the swab, as the violence which it does to the tender surfaces of the throat, and the struggles necessary in order to use it, are of great harm to young children, doing more damage than the local medication does good. The atomizer is, perhaps, the most efficient instrument for local medication. All of its tubes should be of rubber; the mouthpiece should be long and stout, the tip broad and with rounded end, so as not to injure the throat. The water-oil atomizer I find most satisfactory.

Very recently, Dr. Williams (Boston *Medical and Surgical Journal*) has recommended the use of very strong solutions of hydrogen dioxid, from fifty to two-hundred volumes, for local application to the membrane. The argument in favor of this method seems most reasonable, but I have not yet had an opportunity to put it into practice. One posssible danger would seem to be that an agent of such a high degree of saturation would be a cauterant to the healthy mucous membrane.

Many authorities recommend the use of the atomizer, swab, or gargle, only every three or four hours This seems to me, perhaps, as bad a recommendation as can be given. In severe cases no medication can be of effect in thinning the membrane or in preventing its spread, which is not repeated, at least every hour, and in a large number of cases it is necessary to spray the throat at least every half hour or every fifteen minutes. This will require the constant attention of the nurse, but it will often save the patient.

When the nose is affected it should be syringed frequently. For this purpose the same solution may be used as for the throat, but I have found that in the nose the 1 or 2 per cent. carbolic-acid solution is better tolerated by the patient. The wash should be used at least every hour. In forty-five patients with nasal diphtheria this treatment was used, and twenty-four of them (53 per cent.) recovered, while of those who died (twenty-one), two-thirds had laryngeal membrane as a complication.

Thin flakes of membrane, which persist for a long time after the general disease has abated, are best treated by some mild local caustic. The double chlorid of gold and sodium, in 2 per cent. solution, has been of service to me in such cases.

Enlarged cervical lymphatics and enlarged tonsils, which occurred in about 10 per cent. of the observed cases, have yielded most readily and without suppuration, except in two instances, to inunctions of unguentum hydrargyri.

The sequelæ of diphtheria are quite varied. Transient peripheral paralyses are the most common, and may be named in order of frequency as follows: The palatal muscles; the ocular muscles; the peronei, and the tongue. Multiple palsies are rare.

One patient of mine, Case LXVII here reported, a child one year old, made a perfect recovery from the diphtheria, but died three months afterward with what was shown by the post-mortem examination to be a general myelitis. Dr. Eskridge observed this case and now has the specimen.

Since adopting the general methods of treatment which I have described, and especially since beginning the free use of mercurials, paralyses have been quite infrequent in my experience, and it seems probable that the treatment is to be credited with this result. One peculiar case of paralysis seems worthy of record here, as it at first seemed to be truly diphtheric, and illustrates, perhaps, a common error in diagnosis. An infant under observation by Dr. Sewall and myself had a severe attack of diphtheria, and immediately after recovery one leg was useless. Dr. Sewall diagnosticated diphtheric paralysis. I examined the babe, and, from a certain tenderness and fixation of the hip joint, diagnosticated accompanying incipient hip-joint disease. The hip symptoms soon disappeared, however, and I "revised" my diagnosis and agreed absolutely with Dr. Sewall. Treatment seemed unavailing, and after several months we placed the child under Dr. Eskridge's care. His diagnosis was peripheral cerebral hemorrhage. Under appropriate

treatment the cerebral clot was absorbed and the paralysis disappeared.

Diphtheric pneumonia sometimes occurs, and is usually fatal. The only cases that I have observed were two, both in children two years of age, and both of doubtful diagnosis. They were the first of the family to be taken sick. In neither case could I discover membrane, but both died within a short time. In each family there subsequently occurred several cases of undoubted diphtheria. My experience has thus not been in accord with the generally and undoubtedly accurately recorded cases in which the pneumonia has accompanied or followed the diphtheria.

The total number of cases of which I have preserved notes as to treatment is 117; all but about half a dozen of the mildest ones having been treated systemically upon the plan outlined in this paper.

Of the 117, but eighteen patients, or 15.3 per cent., died.

When it is taken into consideration that many of the cases were seen only after several days of neglect or of careless treatment, and that a comparatively large percentage of the cases were of the kind usually described as malignant, the death-rate is to be considered low. That the medicaments employed had something to do with the low death-rate I am convinced; and the frequency of their administration is an item not to be overlooked. Indeed, if there is one point to be insisted upon with unyielding urgency, it is this of large dosage at short intervals in cases of diphtheria. The directions given by some authors to spray the throat every three or four hours, or to give iron or whiskey three times a day, or perhaps every four or five hours, are admirable examples of "how not to do it." It is to be hoped that that kind of teaching and of practice will soon pass away.

In conclusion, I wish to say that there are many other diphtheria remedies which I have tried and found useless and hence have not mentioned. There are many others highly recommended as curative in all cases. These I have not tried, for their alleged unvarying success leads me to the conclusion that they have not been used in the treatment of genuine diphtheria.

It is probable that in a long series of cases, covering several years or several epidemics, no medication now known gives results much better than 85 per cent. of recoveries.

The Proportion of Tuberculous Meat, in nine German cities, varies from 10 to 26 per cent. In England the average is 12.22, that of the London supply being 15 per cent. Bulls and young cattle are almost free, the highest ratio being in cows, which in Midlothian reaches as high as 22 5 per cent.

ALBUMINURIA IN THE APPARENTLY HEALTHY.[1]

By W. H. WASHBURN, M.D.,
of Milwaukee, Wis.

The subject of albuminuria in the apparently healthy continues to be one of considerable importance and interest from more points of view than one. We want to know upon what if any, pathologic condition, of the kidneys or other organs of the body it depends; we want to know what the prognosis is likely to be in a given case; and above all, we are anxious to know if there is any method of management, hygienic or medicinal, which holds out any prospect of resulting in cure.

There has been going on now for some time a dispute as to whether the fluid part of the urine is a filtrate or a secretion. Great interest attaches to this question from the point of view we occupy, for, if the fluid is merely a filtrate, then we may reasonably assent to the opinion that albumin may under some circumstances appear in the urine in the absence of any structural change in the kidney. On the other hand, however, if the fluid is a secretion, we must assume that the secreting structures are endowed with the power of selecting certain elements from the blood and rejecting others; hence, according to this view of the case, the presence of albumin in the urine would invariably indicate structural change in the secreting organ.

A reference to the literature of this subject, since I read my first paper thereon three years ago (The Medical News, April 5, 1890), shows a gradual swing of the pendulum of opinion. For some years previously to that time the tendency had been to regard traces of albumin in the urine as of no particular significance, so far as they might indicate structural change in the kidneys themselves, or from a standpoint of prognosis. Many opinions were on record favoring the issuing of life-insurance policies to men presenting this symptom. At the beginning of this study, some fifteen or eighteen years ago, albuminuria was regarded as synonymous with nephritis, and the prognosis, therefore, necessarily unfavorable. Here was one extreme. When, however, it was found that many of these cases, instead of dying, continued to live, in many instances for years, without developing further unfavorable symptoms, the idea began to take root that albuminuria was not such a grave symptom after all. Gradually, with increasing data, it began to be urged that the presence of albumin in the urine of apparently healthy persons was quite an ordinary thing, and some went so far even as to urge that a small amount of albumin in the urine was a normal condition. But there seems to be a

[1] Read at the meeting of the Milwaukee Medical Society, January 24, 1893.

modifying of these opinions, which were both probably extreme, and we are now undoubtedly more nearly on the right track than ever.

A discharge of muco-pus from the lungs is never a normal occurrence; it may persist for a few days and pass away, and the patient exhibit no further pulmonary symptom, but if the discharge becomes chronic or permanent, then there is something serious the matter. So with albuminuria. I believe that its occurrence is, in every instance, an indication of an abnormal physical condition of the kidneys themselves. It may be transitory in many instances, as will appear in a number of cases I shall detail further along, and never recur, the kidneys suffering no permanent injury from the condition that produced the symptom; or, on the other hand, it may persist for a considerable time—twenty years or more—the probability of cure diminishing with the lapse of time, and the probability of further evidence of structural changes in the kidneys increasing.

We are told that the exciting causes of the form of albuminuria under discussion are: first, diet; second, cold and cold bathing; third, muscular exertion; and fourth, mental strain. I apprehend that all of these several causes act in very much the same way to produce this condition.

As to the dietetic causes: Many experimenters have studied the effects upon the urine of the ingestion of large quantities of egg-albumen. The results have been somewhat uncertain—in some individuals albumin appearing in the urine, and in others not. And the results are still more uncertain for the reason that many of the persons submitting to the experiment were not in apparently good health, in several instances the experimentee afterward dying of chronic nephritis, or a post-mortem examination after death, from other causes, revealing structural changes in the kidneys.

In the case of animals the results are more definite. Dogs have been the favorite animals upon which studies have been made, and the egg-albumen has been introduced by way of the stomach, rectum, and subcutaneous injection, albuminuria resulting from its introduction by all of these avenues. This, of itself, would not prove much, but when the dogs have been killed while suffering from the albuminuria, and the kidneys were examined, it has invariably transpired that a condition of glomerulo-nephritis was demonstrated.

Other articles of diet have been observed to give rise to albuminuria, as, for example, cheese, buckwheat cakes, etc., and it may readily be supposed that when these or other articles of diet are consumed in such quantities as to disturb the digestive process, they may give rise to albuminuria in the same manner as it was shown to result from the ingestion of egg-albumen; or individual idiosyncrasy may account for it.

I believe also that when albuminuria follows exposure to cold or cold bathing, the *modus operandi* is identically the same. I reported one case of this kind three years ago.

The other enumerated causes were muscular exertion and mental strain. Muscular exertion increases the amount of labor thrown on the kidneys in the elimination of the products of retrograde metamorphosis, and in certain individuals may give rise to a transient glomerulitis with accompanying albuminuria. In the case of mental strain the effect is produced in a less direct manner. The primary effect of mental strain, such as is undergone by students in the preparation for examinations, professional men in their multifarious duties, or of severe mental anxiety from any cause, is upon the digestive organs: the stomach and intestines. Digestion is interfered with; the action of the bowels becomes imperfect, so that costiveness or constipation, or both, result; and as a consequence of the resulting presence in the blood of toxic substances, a more or less marked glomerulo-nephritis, with accompanying albuminuria, may follow, which disappear as soon as the patient returns to his normal condition as to digestion. I detailed a case of this kind three years ago, and shall mention more particularly another case in this paper.

We are told that mucin may appear in the urine to such an extent as to respond to the tests for albumin, when there is no serum-albumin in the urine, and that, therefore, it is important for purposes of prognosis to distinguish between albuminuria and mucinuria. I am not in accord with this view, for it is a perfectly fair supposition that in every case of albuminuria there has been a time in its progress when there was an increased amount of mucin in the urine. The renal epithelium being called upon to exercise an unusual activity in the conversion of the albuminous blood-constituents, there would almost of necessity result an increase of the physiologic product, mucin, and hence mucinuria is not only a frequent concomitant, but is probably also a precursor of albuminuria. Therefore, mucinuria must always be regarded with suspicion, and so far as treatment or prognosis is concerned a differential diagnosis between the two is a matter of small practical importance.

I have now on hand, up to January 1, 1893, the records of 1070 urinalyses made in the course of life-insurance examining, and have encountered in this number 38 cases of albuminuria, being in the proportion of 3.55 per cent. These thirty-eight cases may be thus tabulated:

Two died of chronic nephritis; one four years, and one three years after examination.

Four suspected to have chronic nephritis at present, after intervals of from one to four years after examination.

One died of pulmonary tuberculosis fourteen months after examination.

Six were completely lost sight of.

Fourteen are known to be living and in apparent health, after intervals of from one to five years after examination, but the present condition of the urine is unknown, three of these cases being associated with cardiac lesions.

Two are known to be still albuminuric; one of about six months' and one of about four years' standing.

Six are known to have recovered.

Three are known to be still albuminuric, and now under my care, one for two years, one for eighteen months, and one for six months.

In addition to these thirty-eight cases I desire to include in this report two additional cases that came under my care, having been found to be albuminuric on examination for life-insurance, but not having been first examined by me. Including these two cases and the last two groups in the table given, I have eleven cases to detail.

Cases I, II, and III are the three cases reported three years ago, and which have remained well ever since, recent examinations showing the urine to be perfectly normal.

Case IV.—W. G. B., aged thirty-five, of good family and personal history and habits, invested all the savings of his life in a new and uncertain enterprise, which he managed personally. To provide for his family in the event of his untimely death and failure of his business project, he applied for life-insurance, when he was found to be albuminuric; his digestion was impaired; and he was suffering from intestinal flatulence, the microscope showing numerous crystals of calcium oxalate in the urinary sediment. This condition lasted for about six months, when, his business proving very unexpectedly successful, he recovered completely.

Case V.—L. J., a teamster, aged twenty-five, in whose case no particular cause was assigned, and only a few examinations were made, the albumin disappearing from the urine after one week without any treatment whatever.

Case VI.—H., aged thirty-one years, of good family and personal history and habits, had just successfully passed his examinations for a medical degree, and the albuminuria may have resulted from the mental strain incident to that interesting period in his life. The condition persisted for three months after I first discovered it, and then disappeared, and for the past five months his urine has been normal.

Case VII.—H. C. B., aged twenty-seven years, a principal of one of the city schools, had had no previous disease, except pneumonia at the age of twelve years. His parents are living and in good health. His grandparents all reached old age. Albumin was discovered in his urine April 25, 1891. This case seemed to me, at first, to be one of what Pavy has called cyclical albuminuria, for, on several examinations of the urine first passed in the morning, there was no trace of albumin, but later in the progress of the case it was found in the morning urine, as well as in that passed at other times in the day. Physical exercise has always appeared to increase the amount. No appreciable effect has followed the ingestion of food of any kind. Microscopic examinations have been made very many times, always with negative results. The quantity of urine voided daily was perfectly normal, and its specific gravity ranged from 1016 to 1027, but has generally been from 1020 to 1022; and the amount of urea excreted has been practically normal, ranging from 366 grains to 512 grains per day. There have been perhaps a dozen days during the past two years on which there has not been a trace of albumin in the urine, but with these exceptions albumin has been invariably present, though in small amount, which, as already stated, appeared to be slightly increased by a brisk walk. This gentleman suffered from habitual constipation, but otherwise was in a perfectly normal state of health. Correction of the constipation, however, did not appear to exert the slightest influence upon his albuminuria.

Case VIII.—Geo. W., aged seventeen years, is employed out of doors, and is of good family and personal history and habits, his physical appearance indicating robust health. He was examined October 25, 1891, and found to be albuminuric, the amount being comparatively large. This case has now been under observation fifteen months, and during that time quite a large number of examinations have been made. The first urine passed in the morning has never, at any of the examinations, contained albumin. The largest amount ever found was on one cold day in November, 1891, after a long ride on horseback. Microscopic examinations of the sediment have always been negative and the daily amount of urea excreted has been about normal. He has never complained of any subjective symptoms, except on irregular occasions, and then constipation and imperfect digestion were the complaints. On several occasions during the past autumn I have found the urine free from albumin.

Case IX.—J. A. G., aged thirty-six years, is a bookkeeper, of florid complexion and robust appearance, fond of athletic sports. His family and personal history and habits are good, except that there is a slight family predisposition to gout. In childhood he fell from a trapeze, injuring his back to such an extent as to produce osteitis and ankylosis of several of the lumbar vertebræ, but this condition of things has never been an inconvenience to him in any degree whatsoever, and he has always taken a good deal of exercise in gymnasia, and is an enthusiastic lover of foot-ball, which game he frequently engages in. Albumin was first found in his urine August 5, 1892, and since that time frequent examinations have been made. The total amount of urine passed daily has ranged from forty to sixty-six ounces. The specific gravity of the

daily amount has always been 1019 or 1020, and the daily amount of urea has ranged from 432 to 726 grains. The microscope has revealed hyaline tube-casts on several occasions; also numerous crystals of uric acid.

Case X.—W. G. N., aged thirty-two, is of good family and personal history and habits. He came under my observation first on May 5, 1889, having learned, upon applying for life-insurance two years before, that he was albuminuric. For a period of more than a year I watched this case closely, and it is still under observation, though examinations are now only made about once a month. The amount of albumin passed has never been very large. During the six months following the first examination, the first urine passed in the morning was very frequently tested and always found to be free from albumin, but on nearly every other occasion albumin was found in considerable quantity. Microscopic examinations always showed numerous crystals of uric acid, very often crystals of calcium oxalate, and occasionally epithelial cells. The specific gravity was always above 1020 and occasionally as high as 1027. Recent examinations have shown that the albumin still persists in the urine, but the microscope does not as yet show any casts. This, therefore, is a case of more than six years' standing and would appear to be a case of "cyclical albuminuria."

Case XI.—W., aged twenty-eight years, healthy in appearance and of good antecedents, found, on applying for life-insurance last August, that he was the subject of albuminuria. I had examined him for life-insurance on two previous occasions, when his urine was found to be normal, the last examination having been made about two years ago. This is the case of a medical man who is doing a very large and trying practice, who has but little open-air exercise, but who, nevertheless, supposed himself to be in perfect health until it was found that he was suffering from albuminuria. His digestion was and is fairly good; his bowels are rather inclined to be costive—in fact, this condition has been so decided that he has twice been the victim of a fissured anus. The morning urine is not always free from albumin, but has usually been normal, and on perhaps two or three occasions, since last September, the urine has been found to be normal during the day. The microscope has only revealed crystals of uric acid and calcium oxalate. From December 1st to December 10th, there was no albumin found in any specimen of urine examined, and during this time the bowels appeared to be in a more nearly normal state of activity than for some months.

The chief interest in these cases centers in Cases VII, VIII, IX, X, and XI. We may, perhaps, be able to diagnosticate Case X as one of cyclical albuminuria, but it seems to me as though the others must be classed as simple persistent albuminuria. In Case IX, in which we have a history of family predisposition to gout, with gouty manifestations in the patient himself, and excess of uric acid in the urine, we may be justified in the opinion that the man is in the early stage of arterio-capillary fibrosis, and the case must, therefore, be treated as one of incipient nephritis. Case VIII will probably recover; he is now but eighteen years of age, and there have been several occasions on which his urine was normal, it being a noticeable fact that it has been much more albuminous in the winter than in the summer months. Cases VII, VIII, IX, and X have all been treated with various drugs, and have, at times, been placed on diets that restricted the amount of nitrogenous foods, but all apparently to no purpose. They all for several months took strontium lactate in doses of thirty grains three times a day, without the slightest appreciable result. I was led from what I saw in the current medical literature, to expect that some good might result from the administration of the strontium salt, but my experience with it has been very disappointing, not only in these cases, but in several cases of chronic nephritis. General, tonic, and alkaline treatment has been as barren of good results. Saundby says that no cases of albuminuria afford a better opportunity for testing the influence of drugs than those of simple persistent albuminuria, such as are so often met with in the course of life-insurance examining; that although he has met with many such cases, he has never succeeded in curing one of them; that after a few months of unsuccessful treatment, they have usually been lost sight of. You will see by reference to my table that I cannot claim any better results than these; and among those cases in which the albumin has ultimately disappeared from the urine, it is more than doubtful if any drugs employed exercised any influence to that end.

So far as prognosis is concerned, we are no further advanced than we were when Professor Grainger Stewart's *Lectures on Albuminuria* were published in 1888. In these lectures Stewart teaches that in the form denominated *paroxysmal* there is a slight tendency to renal disease; that this result is less likely in those forms due to muscular exertion and to diet, while in the simple persistent form the outlook is less hopeful; though so long as the solids excreted are normal in amount and no vascular changes appear, there is hope. I think, however, that the opinion expressed by Lecorché and Talamon will be acquiesced in by those who have had opportunities to see much of this condition. Their opinion is as follows: "It is impossible to attach any prognostic value to the presence of albumin in the urine. Albuminuria indicates an alteration of the glomerular filtering membrane, transient or permanent; abundant or minimal, it indicates nothing else; it affords us no information as to the profundity and extent, and consequently none as to the gravity of the lesion. To form an opinion of this,

other elements of appreciation and other phenomena, general and local, must be considered conjointly with the albuminuria."

It is not my intention at the present time to enter into a discussion of the question of prognosis; I hope at some future time to make that the subject of a paper, but when we reflect that interstitial nephritis, with considerable proliferation of connective tissue, may continue for some time before tube-casts or renal epithelium appear in the urinary sediment, we shall see that the mere fact that the microscope fails to reveal these elements cannot be assumed to prove that no serious structural changes exist. In the tabulated statement already made, two cases appear which terminated in death from chronic nephritis, one in three years, and one in four years, after examination. In both these cases, repeated microscopic examinations made during several months failed to show any casts or cellular elements in the urinary sediment.

EXPERIMENTS WITH COCAINE PHENATE AS A LOCAL ANESTHETIC.

By C. A. VEASEY, M.D.,

CONSULTING OPHTHALMIC SURGEON TO THE PHILADELPHIA LYING-IN CHARITY AND NURSE-TRAINING SCHOOL, ETC.

So much has been written of late concerning the deleterious systemic effects of cocaine hydrochlorate when used topically upon the mucous membrane or injected by means of the hypodermatic syringe, especially in patients who have organic lesions of the heart or kidneys, that we hesitate to employ it in many cases for fear there may be some idiosyncrasy and that the full physiologic action of the drug may be manifested.

Alarming symptoms often arise from its use, and one often wishes for a drug that would give us the local anesthesia without the probability of the systemic effect.

At the present time it is next to impossible to treat successfully diseases of the eye, nares, pharynx and larynx, or to perform operations upon these parts, without the aid of cocaine; therefore, the manufacturing chemist has been trying to produce some preparation that would possess the advantages without the disadvantages.

On account of the great similarity between the local effects of cocaine and those of phenol, both agents causing local anemia and anesthesia, and because it had been proposed to make extemporaneous mixtures of the two drugs to lessen the systemic effect of the former, it occured to Von Oefele [1] to combine the two substances in such a way as to form a salt perhaps, would have the anesthetic action of both, with the slow-absorbing power of the latter.

In cocaine phenate I believe we have this desired result. It is prepared by Merck, and his description [2] is as follows: "It is a slightly colored substance of *thick-honey consistency*, which readily melts when heated, and whose percentage of cocaine alkaloid is 75. It is readily soluble in a 50 per cent. solution of alcohol. The solution has a faint odor of carbolic acid."

It is extremely deliquescent, my attention having been directed to this quality by my friend Mr. Swartley, who prepared the various solutions for me; it is also soluble in albolene, one of the bland oils produced from the coal-tar group. The dose is from gr. $\frac{1}{12}$ to gr. $\frac{1}{6}$ by the stomach. Locally, "it coagulates the albumin in the tissue, preventing the absorption of the cocaine, thereby prolonging the anesthetic effect and lessening the danger of systemic poisoning." [3]

In this combination, therefore, we possess, theoretically, a drug which has local anesthetic properties with slow-absorbing power, and which should also be slightly antiseptic.

Determining to test for myself the properties of the drug as far as the effect upon mucous membranes was concerned, I had prepared alcoholic solutions and solutions in albolene.

My first experiment was upon my own eye.

The Eye.—On the lower lid of my left eye I placed one drop of the alcoholic solution of 4 per cent. strength, and, as anticipated, experienced a severe burning pain compelling me to close the lids immediately. Upon opening them there was found intense hyperemia of the conjunctiva, lachrymation, and slight photophobia.

[1] Merck's Bulletin, June, 1891, p. 77.

[2] Ibid., February, 1890, p. 10.

[3] Hare: Therapeutic Gazette, January, 1893, p. 19.

In two minutes another drop was placed on the same lower lid, and the symptoms were similar, though not so severe. In four minutes from the time the first drop was instilled there was anesthesia of the conjunctiva of the lower lid, of the lower half of the cornea, and of the corresponding ocular conjunctiva—these being the parts with which the substance had come in contact. The anesthesia lasted for six minutes, and then gradually disappeared. The pupil was very slightly dilated. There were muscular twitchings in the lower lid similar to those caused by an instillation of a solution of eserine, but not so severe or so prolonged in action.

On the lower lid of the other eye the experiment was repeated with a 4 per cent. solution of the drug in albolene. When the the first drop was instilled there was a slight stinging sensation which caused me to close the lids, but lasting for an instant only. The conjunctiva was found to be paler than before the instillation. There was no lachrymation, and no photophobia. In two minutes another drop was placed upon the conjunctiva, and the immediate effect was barely noticeable. In five minutes after the first instillation the conjunctiva of the lower lid and of the lower half of the eyeball was more anemic than before the experiment, and, in addition, the lower half of the cornea was anesthetized so thoroughly that pledgets of absorbent cotton and tissue paper could be rubbed against the parts without producing any sensation whatever. Sensation did not begin to return until ten minutes from the time its absence was first noticed, or fifteen minutes from the beginning of the use of the solution.

The pupil was widely dilated and gradually increased in size for about forty-five minutes, when it had reached the maximum. It was not reduced to the size of its fellow until the following day, though the experiment was conducted early in the morning. There was no paralysis of accommodation in either eye, but the "range" was changed, the near point being carried farther from the eye—in the eye upon which the last experiment was conducted it being about four inches in front of the original near point. My distant vision was slightly impaired, the letters appearing somewhat hazy, though I could still read 20/xx with very little difficulty.

The palpebral fissure was not appreciably enlarged in either eye, and there was no ptosis. The same character of twitching of the muscles of the lower lid was observed as in the other eye.

On the following day, I endeavored to ascertain whether, in the last experiment, it was the cocaine phenate or the albolene that produced the slight burning sensation when first introduced, and for this purpose placed a drop of albolene on the same part of the conjunctiva that, on the preceding day, had been touched by the solution of cocaine phenate in albolene. The result was entirely negative; there was no greater sensation than if a drop of distilled water had been used; thus proving to me that it was the cocaine phenate that caused the peculiar burning sensation when the solution in albolene was introduced, and that this solution had given me the true effect of the drug upon the eye.

THE MOUTH.—With a 4 per cent. solution I brushed the right half of my tongue from the tip as far back as I could well reach. In from two to three minutes the anesthetic action had begun; there was decided numbness of this side. In five minutes the application was repeated, the tongue being held out of the mouth as long as possible, to prevent the saliva from washing the solution away. In five minutes more—ten minutes from the beginning of the experiment—the right side of the tongue was so numb that an instrument drawn over it could not be felt. I then scratched my tongue on the right side with a pointed instrument, and, though the procedure was appreciated, it gave me no pain, as did the same procedure upon the opposite side. Next, I touched the right side of my tongue, at different times, with solutions of sugar and strychnine, but could not perceive the taste, though easily recognized on the left side. The numbness had disappeared and the taste returned in twenty minutes from the first application.

At another time I painted my lips and my gums, and the same anesthetic effect was produced, which reached the maximum in about ten minutes, and had entirely disappeared in twenty minutes.

THE NARES.—In the nares I sprayed some of a 4 per cent. solution in alcohol, and the anesthetic effect was more marked than on the mucous membrane of the mouth. At first there was a stinging sensation, similar to that produced in the conjunctiva, which I attributed, for the most part, to the alcohol in the solution, as spraying the other side of the nose with a solution in albolene, of the same percentage, did not cause more than a momentary burning sensation. The anesthetic effect of the latter solution came on a little later than that of the former, though, as far as could be judged, it reached the same degree of intensity. With the first solution the parts were benumbed almost from the first, the loss of sensation reaching a maximum in about eight minutes, and disappearing entirely in about fifteen minutes. By thoroughly spraying my nasal cavity with my head in such a position as to allow the solution to come in contact with the upper parts, where the terminal filaments of the olfactory nerve are situated, I was able to impair, but not to destroy, the sense of smell. This was destroyed at another time by the use of an 8 per cent. solution, and returned in eight minutes after it had disappeared.

The Larynx and Trachea.—In my own larynx and trachea I was unable to test the effect of the drug, but this was done upon two of my patients, the larynx of one being tuberculous, that of the other being perfectly healthy. In the former, the use of a spray of a 4 per cent. solution of cocaine hydrochlorate, in the larynx and trachea always caused giddiness, slight nausea, nervousness, and insomnia, which lasted during the day and night following the application. Upon spraying this patient's larynx with a 4 per cent. solution of cocaine phenate, I could not produce as great an anesthetic effect as with the hydrochlorate, so I increased the percentage, employing a 6 per cent. and then an 8 per cent. solution. The 6 per cent. solution of the phenate caused about the same effect as the 4 per cent. solution of the hydrochlorate, but the anesthesia, as far as I could judge, lasted a little longer from the use of the former drug. With the aid of this solution I was able to make applications to the tuberculous ulcers in about eight minutes after spraying the larynx.

In the larynx of the healthy patient, the anesthesia was produced in about the same time. In neither case was it possible to say when the effect had entirely disappeared.

While intra-laryngeal medication was facilitated by the use of cocaine phenate, spasm was not prevented, and in this respect the action is similar to that of the hydrochlorate.[1]

The Urethra.—Through the courtesy of one of my surgical friends, I made some observations in the case of a patient in which bougies were being employed for the gradual dilatation of a stricture of the urethra, the canal being so extremely sensitive that at times the bougies could be passed but a short distance beyond the meatus.

I introduced a dram of a 4 per cent. solution of cocaine phenate in albolene into the urethra, holding it there for five minutes, when a No. 30 steel bougie (French scale) was passed without any difficulty, the patient's statement being that he could "feel something," but that was all.

The Ear.—For the sake of making my experiments complete, I regret that I have not had an opportunity, since using the drug, to perform some operation on the ear under the anesthesia produced by it. Suffice it to say that no difference could be distinguished between its action and that of the hydrochlorate, when a drop was placed in the external auditory canal.

Reports of the successful use of cocaine phenate hypodermatically have been published by Vian[2] and by Kyle,[3] though Von Oefele states that he has not yet found a suitable solvent for this mode of administration, the alcoholic solution which he used causing severe pain. I have not had any opportunity to try the albolene solution in this manner, though I believe it will be less painful than the alcoholic.
